OXFORD UNIVERSITY PRESS
NEW YORK TORONTO

PREFACE TO NINTH EDITION

ER thirty-three years, in which he devoted himself to his Textbook, Dr. Frederick Price has resigned the editorship to another. The new editor and all the contributors wish to express their sympathy for him in his recent long and serious illness and their wish that good health and happiness may be restored to him in his retirement. We hope that we have succeeded in making the new edition worthy of British medicine and of Dr. Price.

The purpose and scope of the book remain the same as when it was originally conceived, namely, the presentation of a comprehensive survey of the practice of modern medicine in the form of a textbook, each subject being dealt with in an essentially practical manner, prominence being given to diagnosis, prognosis and treatment. It is our hope that the book will be of service alike to clinical teachers, physicians, general practitioners and students.

Since the last edition appeared we have to record with deep regret the death of our colleagues Dr. Charles R. Box, Dr. Geoffrey Evans, Dr. A. E. Gow, Lord Horder, Professor R. H. A. Plimmer and Mr. Charles Donald, whom we looked forward to becoming here as a new contributor. Mr. Donald had completed his articles on Intestinal Obstruction, Appendicitis and Acute Peritonitis and they appear in the present edition. We feel that they are a better monument to his accomplishments and to his untimely death than any words of ours.

We wish to thank the many contributors to earlier editions who very generously wrote to say that they thought current teaching and opinion in our medical schools could be expressed better by younger men with charge of beds in our teaching hospitals. Accordingly many new names appear in the list of contributors and we extend a most cordial welcome to Dr. E. R. Boland, Dr. R. R. Bomford, Dr. Wallace Rigden, Professor R. B. Hunter, Mr. Ambrose King, Professor B. G. Macgraith, Mr. Brian Russell, Dr. G. A. Smart and Professor Clifford Wilson.

It is a pleasure to state our indebtedness to a number of colleagues who have helped us in making the new edition. We are especially grateful to Dr. Eirian Williams upon whom the work of checking the proofs has mainly fallen. His devotion to this arduous task was equalled only by that of Mr. A. E. Gray of the Oxford University Press who not only shared the burden of correcting the proofs but also compiled the entire index. For the courage, patience and kindness with which they have carried out their secretarial duties it is a pleasure to thank Miss Helen Michie, Miss Jean Lyster and Miss Naomi Wrigley. To our distinguished contributors who have lavished their time and their learning in producing this unique compilation of modern knowledge we wish to express our warmest gratitude and appreciation. For a great deal of help cordially given and also for much forbearance we have to thank our publishers and printers.

SECTION I

INFECTION

Of the three main varieties of disease, infective, degenerative and neoplastic, infective is perhaps the commonest. It is certainly of such frequent occurrence and exhibits so much variety that a brief general account of its origins and nature should precede those of its individual manifestations.

Infection is defined as the successful invasion of the tissues by micro-organisms. "Infective" is an adjective applicable to any such process: "infectious", although used by some writers in the same broad sense, is so often used to denote ready communicability that it is better restricted to this meaning. The micro-organisms responsible belong for the most part to the vegetable kingdom (bacteria) although some to the animal (protozoa), and are the smallest and most primitive forms of life known. It may seem strange that man, the most complex and highly developed of creatures, should be subject to attack by those at the other extreme of the scale of development. It appears less so when one remembers that the principal function of bacteria is to cause the decomposition of dead animal and vegetable material, so releasing their constituents for further use by other living things. In view of this it is not so surprising that some bacteria have evolved the capacity to attack living tissue as well as dead, and have so become "pathogenic".

The stage reached in this evolutionary process varies in different species. Some are "obligatory pathogens", incapable of existence in the body except as causes of disease: such are the virus of small-pox and the bacilli causing tuberculosis and plague. There are other highly pathogenic species to which this definition does not apply, because they may be found in "carriers": these are individuals who have usually recovered from an attack of the disease and are in any case immune to it, but have failed to rid themselves of the micro-organism. Other bacteria are only "facultatively" pathogenic: these include species inhabiting exposed surfaces of the body and the alimentary tract, where they normally lead a purely "saprophytic" existence—i.e., they multiply in secretions, dying superficial epithelial cells and food residues without invading the tissues or causing any harm. In certain circumstances, particularly if they gain access to other parts of the body, such bacteria may assume pathogenic activity.

Another commonly used term requiring definition is "virulence". This is used of pathogenic species to denote the *degree* of their capacity to produce disease, and it may be measured in terms of the numbers of bacteria required to establish infection or to produce fatal infection. Thus the minimum number of hæmolytic streptococci with which a mouse must be inoculated to cause death may be millions or only about five. Virulence in this species is subject to rapid change, and an increase is caused by transference from one host to another, and particularly by a series of such transfers. The same effect operates, although less strikingly, in other species: apart from this, greater or lesser degrees of virulence may be an inherent property of individual trains within a species (the term "strain" is used to denote an individual example of a micro-organism, and is often known by the name of the patient in whom it was found).

the nature of which will be considered shortly, is all important. There are many diseases, such as the common childhood fevers, chicken pox, measles and mumps, which almost everyone must acquire on first exposure to infection, regardless of any other factor whatever. Specific immunity, usually permanent, follows. The degree of immunity—for this may sometimes be relative and not absolute—is a factor in connection with all infection, but it is often overshadowed in importance by others. Indeed many examples of bacterial infection would not have occurred at all had there not been some other condition predisposing to it. Examples of these are the following.

Injury—The interior of the body is normally free of bacteria, and some parts are ill equipped to deal with them. Perhaps the most defenceless tissue is the surface of the central nervous system—hence when the base of the skull is fractured, and bacteria from the naso-pharynx are enabled to enter, meningitis, almost always due to a pneumococcus, commonly results. Similarly a perforating wound of the abdomen is followed by peritonitis due to the escape of intestinal bacteria. Any wound is liable to be contaminated with bacteria from the skin or from the outer world, and much of its treatment is directed to preventing the infection which may otherwise result.

Fluid retention—Another purely mechanical cause of infection, although usually brought about in quite different ways, is obstruction to the escape of some fluid with resulting stagnation. The urinary tract affords the best examples of this retention in the bladder due to prostatic enlargement or in the renal pelvis due to constriction of the ureter is eventually followed by infection, and although this may be eliminated for the time being by treatment it will regularly recur unless the obstruction is relieved. Retained bronchial secretion in bronchiectatic cavities is inevitably infected for the same reason.

Malnutrition—A generally ill-nourished person is thereby rendered more susceptible to many infections, and particularly to tuberculosis. There are more specific forms of malnutrition; deficiency of vitamin A leads to metaplasia of the epithelium of the air passages, which in its turn predisposes to infection. In a sense, malnutrition may be local, the effect of an inadequate blood supply—thus circulatory stasis is the underlying cause of a varicose ulcer and pressure, producing ischaemia, that of a bed sore.

Other diseases—There are many examples of diseases predisposing to others of an infective nature. Diabetes mellitus, cirrhosis of the liver and silicosis predispose to tuberculosis, and hydræmic nephritis to pyogenic infections of serous cavities. Infection, often taking the form of broncho-pneumonia, is a common terminal event in many progressive and incurable conditions, and is particularly liable to develop in old people immobilised in bed, as for the treatment of a fractured femur.

Agranulocytosis—A gross deficiency or actual absence of granular leucocytes in the blood, which occasionally follows the use of certain drugs, deprives the body of a defence whereby its bacterial inhabitants are evidently kept in check, since they then attack the surfaces of the throat and mouth, producing a condition known as agranulocytic angina.

These are only some of the main examples of the causes which underlie many infections, and it will be clear that prevention and treatment should be directed to removal of these causes, when possible, as well as directly to eliminating the infection itself.

RESULTS OF BACTERIAL INFECTION

The tissue changes resulting from infection are in the province of the morbid anatomist, and a textbook of pathology should be consulted for their details. The following account suffices only to define the terms used elsewhere in this book. *Inflammation* is the first result of bacterial invasion, and its cardinal features are the

dilatation of capillaries and the escape from them of fluid and leucocytes. In connective tissue the inflammatory œdema so produced is known as cellulitis; in a serous cavity the result will be an effusion; in a mucous membrane the result is *catarrh*, the most obvious effect, apart from swelling, being an increased flow of secretion.

Some forms of inflammation proceed to tissue destruction. This is of two principal kinds, *necrosis*, or death of an area of tissue, which may be caused by poisonous bacterial products or indirectly, as in syphilis, by vascular changes reducing the blood supply, and *suppuration*, in which tissue is liquefied and the cavity so formed occupied by pus, a fluid containing mainly dead leucocytes and bacteria.

Infection may remain localised, or may spread in any of three ways, by direct tissue continuity, via lymphatics or via the blood. The presence of certain types of bacteria in the blood is called *septicæmia*; in *pyæmia*, fragments of infected clot from veins bordering the focus of infection escape into the circulation and cause septic infarcts elsewhere. *Bacteriæmia* is a term used to denote the presence of bacteria in the blood when this is of not such grave import. It is a constant and merely incidental feature of typhoid fever, occurs in most patients with cerebrospinal fever, and in severe cases of lobar pneumonia. A transient bacteriæmia has been shown to result even from such simple operations as dental extraction and tonsillectomy.

THE RESPONSE OF THE BODY TO INFECTION

The body has two means of repelling bacterial invasion which to a large extent are interdependent. One is by the activity of leucocytes and other phagocytic cells which ingest and may destroy the micro-organisms. The other is by the formation of *antibodies*: these are globulins found in the plasma which have a specific action on bacteria or their products. In this connection a distinction has to be drawn between two different kinds of infection. In one, of which the best examples are diphtheria and tetanus, the bacteria form a potent *exotoxin*—i.e., a toxin or poison which is discharged by the growing bacterium into its surroundings and is carried to parts of the body where it causes damage remote from the focus of infection. The whole of the damage to tissue in these diseases is caused by this toxin, and the response of the body is the formation of an antibody, antitoxin, which neutralises this. Most bacteria form no such toxin, although they contain an *endotoxin* which is liberated when they are destroyed: these produce their effects directly by their presence and multiplication in infected tissue. Infection due to such bacteria extends much more widely, and is sometimes described as *invasive* in contradistinction to the localised exotoxin-forming type. The response to such infection is the formation of antibodies with a direct action on the bacteria themselves: these are agglutinin, which clumps and immobilises them—an important factor in checking spread—opsonin, which enables phagocytes to attack them, and bacteriolysin, which can actually cause their dissolution.

Antibodies act only on the bacteria in response to which they are formed. Their development is an essential factor in natural recovery, and subsequent immunity depends on their continued presence in the blood.

IMMUNISATION

Specific immunity having this basis not only results from an attack of the disease but may be produced artificially with much less disturbance or none. Artificial immunisation is of two kinds:

Passive.—This is the administration of serum, either of an immune human being or, more commonly, of an animal rendered highly immune by the second of these methods. The necessary antibody is thus supplied ready-made, and the term "passive" denotes the fact that the recipient takes no part in its formation. This is an

emergency measure, and its effect is of short duration, the extraneous globulin introduced being lost, as are other labile constituents of the body, within a short time. It may be used in either prevention or treatment. Its preventive use is certain of effect when the serum is one containing antitoxin. This type of antibody is accurately measurable and its unit is the subject of an International Standard. An adequate dose of diphtheria or tetanus antitoxin protects absolutely against these diseases for about 10 to 30 days, according to the amount given. Antitoxic sera are less consistently effective in treatment because they cannot repair damage already done by toxin to susceptible tissue cells, but they achieve their purpose if given early, before this damage is too extensive. Antibacterial sera have been used almost exclusively for the treatment of established infection, and are in general less effective, although the antipneumococcal serum formerly used in pneumonia was an exception. It so happens that most infections originally treated in this way are now amenable to chemotherapy.

Active.—The object of active immunisation is to stimulate specific antibody formation by the recipient: when this process has been initiated, it continues as it does after a natural attack of the disease, although usually not for so long. The only stimulus which will serve is the toxin or the micro-organism itself, according to the class to which the infection belongs, and either must be rendered relatively harmless before it can be injected. Toxin can be rendered harmless without loss of immunising capacity by conversion to toxoid, and diphtheria and tetanus toxoids are used, the former in several different forms, for active immunisation against these diseases. For invasive infections, the micro-organism must be used. It can be rendered harmless by being first killed by heat or chemical treatment (typhoid vaccine), by being deprived of virulence by prolonged artificial cultivation under abnormal conditions (B.C.G. vaccine for tuberculosis) or by habituation to growth in another animal species (vaccination against small-pox affords an example of this). Whether dead or living but "attenuated" by either of these processes, it elicits a reaction similar to that of the natural disease, antibody being formed. The resulting protection against some diseases, including small-pox, is absolute for several years: in connection with others it can only be said that the likelihood of developing the disease is substantially reduced.

These methods are not applicable to all infections. Some, like chicken-pox, are not worth preventing: for others, either because a variety of immunologically distinct micro-organisms can cause them, or because no technique for preparing a harmless but effective vaccine has yet been devised, we are unable to produce immunity.

and doubling the dose each time until a therapeutic quantity is reached : the principle of this method is that free antibody is progressively neutralised until, by the time a large dose of serum is given, none is left to combine with it.

The risk involved in sensitisation affords a strong reason for not administering therapeutic serum of animal origin except for clear indications, although the highly refined antitoxic sera now available, consisting largely of antibody globulin, are certainly less dangerous than the cruder products of the past. Whenever foreign serum is administered, adrenaline and a hypodermic syringe should be instantly available, and 1 ml. of a 1 in 1000 solution should be injected forthwith if signs of shock develop.

Serum sickness is a delayed and much less serious effect of administering foreign serum, and is believed to be due to reaction between antibody formed to it and the small amount of foreign protein still circulating at this stage. The usual time of onset is about the eighth day after injection, and the features are urticaria with itching and moderate fever, sometimes with swollen and painful joints. Only symptomatic treatment is necessary.

ALLERGY

Allergy was defined by von Pirquet, who coined the word, simply as "altered reactivity", and to accept this definition is to condone an indiscriminate use of the term which has rendered it almost meaningless. Confusion would be avoided if its use were more restricted: the following are two distinct phenomena to which the term definitely applies.

Bacterial allergy.—In various microbic infections and parasitic infestations the tissues become sensitised to the causal agent of the disease, and react to it, or to an extract of it, with inflammation and œdema. The change responsible is in tissue cells, and is not dependent on the presence of an antibody in the blood: thus although anaphylactic sensitivity is transferable from one individual to another by serum, allergic is not. The usefulness of this state in resisting infection is the subject of very divergent views; it is certainly distinct from immunity, although degrees of both may co-exist. Its usefulness to the physician is indisputable, since it is the basis of diagnostic tests, the best known of which is the tuberculin reaction. There are similar tests for the diagnosis of undulant fever, glanders, lymphogranuloma inguinale, hydatid disease and trichiniasis.

Some authorities take the view that a reaction of this type may be the basis of naturally occurring disease; rheumatic fever, for example, is regarded by some as representing an allergic reaction to the hæmolytic streptococcus or its products. Some forms of nephritis and even pneumonia have been credited with a similar basis. It is much easier to postulate such an origin for a disease than to prove it.

Allergy to inanimate foreign material.—A common variety of asthma and some skin diseases appears to be the result of sensitisation to elements, usually proteins and often of animal origin, contained in foods, dust, etc.; the responsible material can be identified by skin tests with extracts. Sensitivity to drugs may be of the same nature. Comparatively simple chemical compounds are incapable of acting alone as the inciting agents of such reactions, but they can do so when they combine with plasma protein: a substance which, when combined with a protein, confers such specificity on it is known as a haptene. Penicillin, to which such reactions are being seen with increasing frequency, is known to circulate in the blood partly in such a combined form.

ANTIBIOTICS

Antibiosis, the antithesis of symbiosis, may be defined in broad terms as the formation by one living thing of a substance detrimental to another. The word is used chiefly in reference to such antagonism within the plant kingdom and more particularly of relationships between species of micro-organisms, both bacteria and fungi. That some micro-organisms produce substances antagonistic to the growth of others has been well recognised for over 70 years, the first observation on this subject having been made by Pasteur himself. Many attempts were made during this period to exploit such products in therapeutics, with little success, owing chiefly to the gross impurity of the materials used. The first antibiotic to be purified and shown to exert a systemic as well as a local action was gramicidin (tyrothricin), isolated from *Bacillus brevis* by Dubos of New York. The example set by his work was largely responsible for the isolation and therapeutic study of penicillin and hence indirectly for the further developments of which this chapter is an account.

PENICILLIN

Penicillin, the product of a green mould, *Penicillium notatum*, was discovered by Fleming in 1929. Early attempts at purification failed, and it was not until 11 years later that Florey and Chain overcame the difficulties imposed by the instability of the natural product, and extracted from cultures material suitable for experimental, and later clinical, study. The properties thus revealed were so astonishing that immense efforts were concentrated during the latter part of the War of 1939-1945 on producing enough penicillin for the treatment of battle casualties. Supplies became adequate for this purpose in 1944, and civilian use was also expanded until a free market was established in 1946.

(growth preventing), penicillin is actively bactericidal (lethal). Like them, however, it can exert this action only on multiplying bacteria, the more rapidly multiplying the better. This explains the dramatic effect of both forms of chemotherapy on acute infections, and their lesser efficacy in the treatment of chronic infections and carrier states. These facts indicate that penicillin, like the sulphonamides, arrests some vital process in bacterial metabolism, the precise mechanism is not yet known. The action of penicillin is unique in being exerted fully in any environment found in the body, that of many antiseptics, as is well known, is diminished in the presence of various body fluids, and even that of the sulphonamides is neutralised by substances occurring in pus. There are no such limitations to the action of penicillin, unless its environment is such as actually to destroy it (as by acid in the stomach or bacterial enzymes in the lower bowel) its antibacterial power is constant.

Susceptibility to the action of penicillin varies very widely among different bacterial species. It follows that only those infections due to more susceptible bacteria are suitable for treatment, and that the nature of the infection should preferably be known before treatment is begun. This may be self evident, as in gonorrhœa or carbuncle, in conditions such as pneumonia, septicæmia or meningitis it probably will not and specimens for bacteriological examination should always be obtained before treatment is begun.

The following table gives a list of the principal pathogenic micro-organisms classified in the hitherto conventional manner as sensitive or resistant to penicillin.

Sensitive

Gram negative cocci

- N gonorrhœa*
- N meningitidis*

Gram-positive cocci

- Strep pyogenes*
- Staph aureus*
- Strep pneumoniae*
- " *viridans*

Gram-positive bacilli

- B anthracis*
- C diphtheria*
- Clostridia (welchii, etc.)*

Spirochetes

- T pallidum*
- T vincenti*
- L icterohæmorrhagiae*

Miscellaneous

- Fusiformis* and related organisms
- Actinomyces*
- Streptobacillus moniliformis*
- Erysipelothrix rhusiopathiae*
- Ornithosis virus

Resistant

Strep faecalis

Gram-negative bacilli generally, including the whole of the genera *Hæmophilus*, *Bacterium*, *Salmonella*, *Shigella*, *Pseudomonas*, *Proteus*, *Brucella* and *Pasteurella*

Mycobacterium tuberculosis

Yeasts and moulds

Viruses generally

1 unit per ml. The following is a list of important species in order of diminishing susceptibility.

				Approximate concentration of penicillin in units per ml required to inhibit growth
<i>N. gonorrhœæ</i>	0.002-0.005
<i>Strep. pyogenes</i>	0.01
<i>Staph. aureus</i>	0.02
<i>Cl. welchii</i>	0.1
<i>H. influenzae</i>	0.5-5.0
<i>Strep. faecalis</i>	2.0-5.0
<i>Proteus vulgaris</i>	8.0
<i>Salm. typhi</i>	5.0-20.0
<i>Bact. coli</i>	30.0->100.0
<i>Shigellas</i>	>100
<i>Ps. pyocyanea</i>	>1000
<i>Myc. tuberculosis</i>	>1000

The importance of recognising these grades of susceptibility is that in certain situations a very high local concentration of penicillin can be attained, which is capable of destroying bacteria ordinarily classed as resistant. Thus, intrathecal injection will produce in the cerebrospinal fluid a concentration adequate for the treatment of meningitis due to *H. influenzae*. The same is true of the urinary tract: penicillin is excreted in the urine in high concentration, and may cure an infection due to any organism inhibited by 50 units per ml. or less.

Although the susceptibility of some bacterial species is constant within narrow limits, in others it varies from strain to strain. This is particularly true of staphylococci, which sometimes possess naturally a high degree of resistance. Variations in susceptibility are also seen among strains of *Strep. viridans* and *Actinomyces*. It is often advisable to test susceptibility in the laboratory before embarking on treatment, if only to decide on dosage. Sometimes the result with a staphylococcus will indicate that treatment is likely to be useless.

The clinical indications for the use of penicillin are too numerous to be detailed here, and frequent references to them will be found in the chapters on individual

intervals, which is now more common practice than giving smaller doses at short intervals, produces wide fluctuations in the blood level, alternating with periods during which an effective level is absent. This is at least theoretically undesirable in some conditions, but the high levels immediately following a dose are believed to promote diffusion into tissue fluids in areas of inflammation and particularly into isolated foci of infection: in these, penicillin persists much longer than in the circulation.

When a continuous effect is required, a different form of penicillin may be preferred. The history of "repository" preparations, from the injection sites of which the drug is slowly absorbed, began with the suspension of soluble penicillin in an oil medium, but made a great advance with the introduction of procaine penicillin, an equimolecular compound of the two substances which has a much lower solubility. This is usually administered as a watery suspension, and although the size and shape of the crystals determine their rate of solution, which can also be further delayed by suspending them in oil, a dose of 300,000 units of any such preparation should maintain a therapeutic concentration in the blood for at least 24 hours and will often do so for longer. The maximum concentration is reached with such preparations in about 4 hours and is much lower than that produced by sodium penicillin. For still more prolonged effects—extending even to several weeks after a large dose—preparations of N, N'-dihenzylethylenediamine dipenicillin may be used.

Another method of prolonging effect, but more often used to sustain a higher blood level than the dosage would otherwise produce, is to administer a substance which impedes renal penicillin excretion. Those used successively have been sodium *p*-aminohippurate, 4'-carboxyphenyl-methane-sulphonanilide (Caronamide), and probenecid (Benemid): the latter is now usually preferred.

Oral administration is an alternative particularly suitable for young children, and may be used in adults if the infecting organism is highly sensitive and the condition not dangerous. When penicillin is swallowed, much of it is destroyed by the gastric acid, and thereafter absorption is erratic and incomplete; even in patients with achlorhydria only a variable amount, not often exceeding one-fifth of the dose, appears in the urine. Various special forms of penicillin manufactured for this purpose have little of the advantage claimed for them: recent observations have shown that simple tablets of soluble penicillin, possibly including a buffer, are absorbed as well as anything else. They are better absorbed if taken before meals than after.

It is difficult to lay down any general rule about the duration of treatment, except that it should be continued until the infection is overcome. The duration varies from a few hours for gonorrhoea to 6 weeks or more for subacute bacterial endocarditis. The subsidence of fever is often the surest guide, but is not infallible. A recurrence may take place if treatment is stopped too soon after the temperature falls; this often occurs in pneumonia and acute streptococcal throat infections. The explanation of such recurrences is that penicillin destroys most of the micro-organisms before the ordinary immunity mechanism has come into play; a few survivors will thus multiply without restraint and the attack is repeated.

Local administration.—If the site of infection is an accessible surface or body cavity, local administration may be indicated, either alone or combined with systemic. Technique is all-important, and must be such as to secure persistence of effect. Thus skin infections or superficial wounds or burns may be treated with a cream made up with a suitable base from which penicillin is slowly liberated and absorbed. Infections of the nose and naso-pharynx, including carrier states, are susceptible to the action of a snuff containing 5000 units of calcium penicillin per gramme of sulphathiazole. Mouth and throat infections can be treated by the continuous sucking of penicillin pastilles, preferably in a gelatin base. Inhalation of a solution is useful for certain infections of the bronchi. Lamellæ or solution frequently instilled are used in conjunctivitis.

Closed body cavities afford special opportunities for effective treatment; a solution can be injected into them which will exert not only a prolonged and powerful local effect, but even a systemic one if the dose is large enough, since slow absorption takes place through inflamed serous and other surfaces. Such injections may be made into inflamed serous sacs, joints and abscess cavities generally. Intrathecal injection may be indicated in meningitis. 10,000 units daily by this route will maintain a cerebrospinal fluid concentration adequate for the treatment of susceptible infections. Some authorities now prefer to enable penicillin to traverse the blood-brain barrier by giving very large and frequent doses intramuscularly, such as 2,000,000 units every 2 hours.

Toxic effects—Penicillin is by far the least toxic chemotherapeutic agent known, this is its most astonishing property, and an important factor in its therapeutic success. Enormous doses—such as 40,000,000 units a day—have been given without ill effect. There are no recorded instances of damage to the bone marrow, liver or kidney, such as has occasionally to be feared following the use of many other potent antimicrobial drugs. On the other hand, sensitivity to penicillin is increasing in frequency, and causing difficulty in administration. In patients sensitised by previous treatment—or, it is said, by suffering from skin mycoses—an injection of penicillin may produce urticaria and fever. Occasionally it may result immediately in vasomotor collapse, which has even been fatal. Sensitised patients may be recognised by injecting a small dose intradermally, which causes wheal formation within a few minutes. It is a wise precaution to apply this test to any patient giving a history of previous reactions or suffering from asthma or other allergic condition. Such reactions can be prevented in sensitised patients by adding an anti-histamine compound to the penicillin to be injected.

STREPTOMYCIN

Streptomycin, extracted from *Actinomyces griseus*, the antibacterial properties of which were first described by Waksman and his colleagues in 1944 was the first successful product of a world wide and systematic search for further antibiotics which began when the value of penicillin was first recognised. It is of more complex chemical structure than penicillin, the commercial product is a salt of the natural base. This is a white powder, freely soluble in water, although not soluble in as high a concentration, in terms of its activity, as penicillin. It is measured by weight, 1 g of pure streptomycin being equivalent to 1 000 000 units as originally defined.

Action on bacteria—Streptomycin like penicillin, is actively lethal to bacteria. The mechanism of its action is certainly different, but so far unknown. A neutral or alkaline medium is necessary for it, whereas penicillin is at least equally active a little on the acid side of neutrality.

The merit of streptomycin is that it is effective against certain bacteria which are resistant to penicillin. The most important species among these is the tubercle bacillus, the rest are chiefly Gram negative bacilli including most of the intestinal pathogens, *Haemophilus influenzae* and *pertussis*, the *Brucella* group *Pasteurella* (plague) and *Pseudomonas*. It is also active in lesser degree against most of the Gram positive species which are also sensitive to penicillin.

The main drawback of streptomycin is that bacteria originally sensitive to it may rapidly acquire a high degree of resistance during treatment. This resistance may be acquired within 2 days or even less, and is of such a degree that further treatment is quite useless.

Administration—Streptomycin given by intramuscular injection is absorbed and excreted rather more slowly than penicillin, it is therefore usually administered at intervals of 6 or 8 hours or once daily during prolonged treatment, as for tuberculosis. The total daily dose is usually 1 g for a long course but larger amounts may be

given for short periods. Distribution in the body is similar to that of penicillin; the drug does not enter the cerebrospinal fluid, and is excreted by the kidneys. There is a striking difference from penicillin in the behaviour of the drug when given orally. It is not destroyed in the stomach, but neither is it absorbed; it is excreted almost quantitatively in the faeces, and acts as a powerful intestinal antiseptic, almost completely suppressing the coliform flora.

Streptomycin can also be administered locally in various ways; intratubercal injection is the most notable example of this. The local treatment of large collections of pus, such as empyema, is disappointing; the acid reaction of the exudate probably explains this.

Indications.—Tuberculosis in its more acute forms and some of its more chronic is the outstanding indication for this drug. This is not the place to enter into any further detail on this subject, but it should be added that the present practice is never to give streptomycin alone, but to administer at the same time either isoniazid or sodium aminosalicylate, either of which has an independent action on the tubercle bacillus.

Formerly many infections of various kinds due to Gram-negative bacilli were indications for streptomycin treatment. Its use for these purposes has diminished for two reasons: many strains of such bacteria are now completely resistant to it, and other antibiotics have been introduced which produce a similar effect with less trouble. The former consideration does not apply to tularæmia or plague, since these are acquired from animals in which previous contact with the drug will not have occurred; both are unequivocal indications, unless one of the later antibiotics be preferred for the treatment of tularæmia. In any other infection the sensitivity of the causative organism should be tested. If the result of this test is satisfactory, streptomycin may be used for infections by coliform bacilli (*Bact. coli*, *Bact. aerogenes*, *Ps. pyocyanea*) wherever situated: these may take the form of a septicæmia, meningitis or a urinary tract infection. For the latter it is important to render the urine constantly alkaline before treatment is started. Pneumonia due to Friedländer's bacillus is another strong, if uncommon, indication. Streptomycin acts synergically with penicillin against some bacteria, notably *Str. faecalis*: endocarditis due to this organism calls for treatment with both drugs. This should be no excuse for administering this combination indiscriminately on the general principle that it is superior to penicillin: much harm can be done by such unnecessary use.

Toxic effects.—Excessive doses of streptomycin can cause liver degeneration and various nervous system effects, but dosage has to be kept within strict limits mainly because of possible damage to the eighth nerve. There is little danger of this from a course of treatment lasting a week or less, and it does not often result from a longer course if the dose is restricted to 1 g. daily. There are exceptions to these rules, some at least of which have been patients with unrecognised or unheeded impairment of renal function: excretion of the drug is then delayed and a given dose produces higher and more sustained blood levels. Streptomycin more often damages the vestibular branch, although the auditory may also be affected, and the consequent vertigo or deafness develops during administration. Dihydrostreptomycin, originally thought to be non-toxic, causes damage to the auditory branch which may not betray itself until well after the course is finished. Since the damage is usually permanent, this danger affords a very strong reason for not using this drug except for clear and serious indications. The suggestion that a combination of both forms is safer has yet to be fully verified.

CHLORAMPHENICOL

Two further important antibiotics, also derived from soil actinomycetes, were discovered in 1948: of these it is convenient first to deal with Chloromycetin. This is a product of *Streptomyces venezuelæ*, and was at first manufactured from cultures

of this mould. It was then found possible to synthesise it on a commercial scale, and the synthetic product, indistinguishable in every way from the natural, is known as chloramphenicol. It is the only antibiotic of therapeutic importance which can be produced in this way. Its solubility in water is low, and its action, like that of the tetracyclines, mainly bacteriostatic.

This drug opened a new chapter in antibiotic treatment by virtue of its mode of administration. Like its principal successors, it is simply administered in capsules

SENSITIVITY OF PRINCIPAL PATHOGENS TO SIX ANTIBIOTICS

Average concentration attained in blood on ordinary dosage ($\mu\text{gm/ml}$) ..	0.3	10	4	10	4	2	2

The inhibitory concentrations stated are those normal for the species; in many cases they are subject to wide variation particularly in the direction of greater resistance.

Oxytetracycline behaves very similarly to chlortetracycline: it is somewhat more active against *Ps. pyocyanea*.

Carbomycin behaves similarly to erythromycin, but is less active against some organisms and attains lower blood concentrations.

by the mouth. Absorption from the alimentary tract is satisfactory if not complete, and excretion (mainly by the kidney, and mainly also in an inactive acetylated form) is comparatively slow: hence 4 daily doses of 0.5 g. will maintain an adequate concentration in the blood continuously. Chloramphenicol appears in glandular secretions, particularly those of the air passages, and regularly attains concentrations in the cerebrospinal fluid equal to about one-third of those in the blood, an advantage possessed in this degree by no other antibiotic.

Indications—The most striking advance achieved by the discovery of this and other antibiotics is the provision of specific and regularly effective treatment for all forms of typhus. The remarkable efficacy of chloramphenicol was first demonstrated in the treatment of scrub typhus in Malaya: there is now evidence that this applies

to all rickettsial infections, including Q fever. Chloramphenicol is also effective against the viruses of psittacosis, lymphogranuloma inguinale and "primary atypical pneumonia".

By its action on bacteria also chloramphenicol qualifies as one of the "broad spectrum" antibiotics: a variety of both Gram-positive and Gram-negative species are susceptible to it. The susceptibilities of some important species to this and other antibiotics are stated in the Table. The minimum inhibitory concentrations given are necessarily only approximate; these depend on the conditions of the test determining them and vary also with the strain of organism used. In general, chloramphenicol is less active than penicillin or chlortetracycline against Gram-positive organisms, but more so against Gram-negative. Thus its principal sphere of usefulness is for treating infections due to certain Gram-negative bacilli. An outstanding example is typhoid fever: although other antibiotics might be expected from their *in vitro* performance to have some effect in this disease, chloramphenicol far exceeds them in therapeutic activity. Another strong indication is *H. influenzae* meningitis, because both of the extreme susceptibility of this organism and of the relatively high concentration which the drug attains in the cerebrospinal fluid. It may also be used successfully for undulant fever. Its choice for a variety of other purposes for which alternatives exist will depend on the view taken with regard to its toxicity.

Toxic effects.—Like other orally administered antibiotics, chloramphenicol is liable to cause nausea or vomiting and diarrhoea, especially if given in full doses for more than a few days. Unlike any other, it can also cause aplasia of the bone marrow, and a consequent deficiency of all formed elements in the blood: such patients exhibit hæmorrhages and rapidly progressive anæmia which are usually fatal, although the marrow recovers in some after a series of transfusions. Occasionally the only effect produced is agranulocytosis, red cell and platelet formation being unaffected.

The true frequency of this complication is still unknown: in some hospitals or practices several examples have been seen, suggesting a fairly high incidence, whereas others profess to have treated thousands of patients with no ill effect. Nor is there any unequivocal information about the system of treatment most liable to cause marrow damage. Excessive doses, prolonged treatment or repeated courses have sometimes preceded it: in other cases a quite small total dose has been responsible, and it seems necessary to assume that idiosyncrasy is a factor. Whatever view may be taken of this risk, it undoubtedly exists, and chloramphenicol should certainly not be prescribed except for some definite and serious indication. To pay with one's life for the doubtful benefit conferred by this drug in the common cold, as some patients have done, is asking too much.

THE TETRACYCLINES

CHLORTETRACYCLINE

Chlortetracycline (Aureomycin), also discovered in 1948, is a golden yellow substance formed by *Streptomyces aureofaciens*. Chlortetracycline hydrochloride, the form chiefly used in therapeutics, gives highly acid solutions which are much less stable than those of other antibiotics. The intramuscular injection of such a solution causes severe pain, but the drug can be suitably dissolved in a large volume of buffered solution for intravenous injection. The ordinary method of administration is in capsules by the mouth, and dosage and pharmacological behaviour are similar to those of chloramphenicol, with the following differences: the blood levels attained are rather lower, and those in the cerebrospinal fluid distinctly so, the drug is excreted in the urine in active form and, owing either to excretion in the bile or to incomplete absorption, has a greater suppressive effect on the bowel flora.

Indications.—Chlortetracycline has a comparable effect to that of chloramphenicol in all rickettsial and certain virus infections and in undulant fever. It is more active than chloramphenicol against Gram-positive cocci, and thus a particularly valuable substitute for penicillin in staphylococcal infections resistant to the latter. Its action on pneumococci, streptococci, *H. influenzae* and the pneumotropic viruses enables it to be used indiscriminately for any form of pneumonia. It has also been successfully used for gonorrhœa, syphilis, peritonitis, gas gangrene, urinary infections and actinomycosis.

Toxic effects.—These are limited to gastro-intestinal disturbances, unless excessive doses are given, particularly by the intravenous route, when there may be some damage to the liver.

OXYTETRACYCLINE

Oxytetracycline (Terramycin), formed by *Streptomyces rimosus*, and introduced in 1950, closely resembles chlortetracycline both in chemical structure and in therapeutic activity. It is colourless, less soluble and more stable than chlortetracycline, administered by the mouth or, if necessary, intravenously in similar dosage, and attains blood levels for a given dose intermediate between those produced by chloramphenicol and chlortetracycline. Indications for its use are almost identical to those for chlortetracycline. Gastro-intestinal disturbances have been the only toxic effects observed.

TETRACYCLINE

It is known that the molecular structures of chlortetracycline and oxytetracycline are identical, but for the presence of a Cl atom in the former and an OH group in the latter. The same molecule without either of these additions is tetracycline, which can be prepared from one of the other drugs and is also formed directly by a recently discovered mould. It has a very similar therapeutic action, but is said to be much less liable to cause nausea or vomiting and diarrhœa, an important advantage in some patients, including any who have to take such a drug for some length of time, as, for instance, in the treatment of brucellosis.

ERYTHROMYCIN AND CARBOMYCIN

Erythromycin (Ilotycin) and carbomycin (Magnamycin) are recently introduced antibiotics of as yet unknown structure. From their antibacterial spectra and the completeness of cross-resistance between them it is evident that they must be closely related: erythromycin is the more therapeutically active of the two in infections which have hitherto been studied. Their spectrum resembles that of penicillin, streptococci, staphylococci and other Gram-positive organisms being highly susceptible and Gram-negative species except of the genera *Haemophilus* and *Neisseria* relatively resistant. The therapeutic activity particularly of erythromycin, has been confirmed clinically in pneumococcal infections (pneumonia), haemolytic streptococcal (acute sore throat) and staphylococcal (various). Since penicillin will usually serve for the two former, it seems that these antibiotics will be mainly useful in staphylococcal infections unresponsive to other drugs. They are administered by the mouth and behave pharmacologically in much the same way as the tetracyclines: gastro-intestinal disturbances are the only toxic effects hitherto noted.

ANTIBIOTICS FROM BACILLI

The genus *Bacillus* (aerobic Gram-positive sporogenous rods) includes several species which form powerful antibiotics; indeed the first such substance ever shown to exert a systemic antibacterial effect was gramicidin, derived from *Bacillus brevis*.

Antibiotics formed by *Bacilli* are polypeptides, and all are toxic in some way and to some degree, often so much so as to preclude their systemic use, although local application may be useful and is harmless. The most promising are bacitracin and polymyxin, the antibacterial activities of which are stated in the Table. It is strange that two substances of like derivation and similar structure should have such different action.

Bacitracin is chiefly active against streptococci and other Gram positive cocci. Since penicillin and other safer antibiotics will usually deal with these organisms, its use is not often indicated, but may be so, for example, in subacute bacterial endocarditis due to an atypical streptococcus resistant to other drugs. Bacitracin is liable to cause renal tubular degeneration, and many patients given it develop albuminuria; this is said usually to disappear after administration has ceased. Oliguria and nitrogen retention have occurred in patients given large doses or having previously damaged kidneys.

Polymyxin—There are now known to be five forms of polymyxin; those designated B and E are the most suitable for therapeutic use, and are less liable to cause renal damage than bacitracin. Polymyxin has little action on Gram positive organisms but is highly active against some Gram negative species including *Ps. pyocyanea*, which is notoriously resistant to most other forms of chemotherapy. Meningitis due to this organism is a strong indication for polymyxin, and intrathecal injection is safe. Urinary infections due to this or similar bacteria resistant to other drugs may also call for it.

Bacitracin and polymyxin have both to be administered by injection.

COMBINED TREATMENT

It is sometimes advisable to give two antibiotics together, but the indications for this should be precise and clearly understood. Such treatment may be required for any of three reasons. The infection may be mixed, and hence unresponsive to any single drug, as in peritonitis, which may be treated with penicillin and streptomycin. It may be important, particularly during prolonged treatment, to prevent the acquisition of resistance by the bacteria to the drug used, and the simultaneous action of a second drug tends to prevent this; the best example is tuberculosis, where the administration of a second drug—not in this case usually an antibiotic—is now considered imperative. Thirdly, two drugs together may exert a synergic effect, i.e., one greater than the sum of their separate effects. An example of this is the action of penicillin with streptomycin in *Str. faecalis* endocarditis; this combination alone is completely bactericidal to this organism, and in order to cure this infection, nothing short of total extermination of the streptococci in the vegetations will suffice.

Unfortunately the effect of combining two antibiotics may sometimes be quite the opposite. The bactericidal drugs (penicillin and streptomycin) exert this effect only on multiplying bacteria, and the bacteriostatic (chloramphenicol, chlortetracycline and oxytetracycline) prevent multiplication. Hence in a combination of one from each of these groups, the action of the bactericidal drug may be inhibited. It is uncertain how far this effect operates under clinical conditions, but a clear example of it has been seen in the unsuccessful treatment of cases of pneumococcal meningitis with chlortetracycline and penicillin, when a series treated with the same dose of penicillin alone had a much lower mortality. In general such combinations should be avoided, and in difficult cases an elaborate form of *in vitro* test may be necessary to decide what drugs will exert the desired effect.

ACQUIRED BACTERIAL RESISTANCE

Several references have already been made to the fact that bacteria formerly susceptible to an antibiotic may become resistant to it, sometimes to a degree

These substances are all suitable for administration by mouth and are absorbed well from the small intestine. The absorption, however, of sulphapyridine is somewhat irregular.

With the exception of sulphacetamide, and to a less degree sulphanilamide, these compounds are very sparingly soluble in water, but sodium compounds are made which are very soluble in water and can be administered either intravenously or intramuscularly, although their great alkalinity renders them very damaging to the tissues and great caution must be exercised in their use.

Another group of sulphonamides are absorbed poorly from the intestinal tract.

Sulphaguanidine is produced by substitution in the sulphonamido group with guanidine.

Others are made by acetylation of the *p*-amino group with succinic and phthalic acids. These compounds are known as succinylsulphathiazole and phthalylsulphathiazole.

Sulphaguanidine is absorbed somewhat better than the other two, and although it exerts its major effects in the intestinal tract, up to 60 per cent. may be absorbed and its systemic effects, toxic reactions and insolubility in the urine cannot be ignored. In the case of succinylsulphathiazole and phthalylsulphathiazole absorption is negligible, less than 5 per cent., and toxic manifestations are rare. A greater concentration can therefore be produced in the intestinal tract.

This antibacterial action is believed to be due to an effect on the bacterial enzyme system. Bacteria require *p*-aminobenzoic acid for their growth, and it has been shown that sulphanilamide and *p*-aminobenzoic acid are competitive antagonists, competing for the same enzyme receptors. The bacteriostatic action of sulphonamides can be prevented by the addition of *p*-aminobenzoic acid even in small quantities and suggests that the bacteria have a high affinity in their enzyme systems for this substance and this presumably accounts for the relatively great concentration of sulphonamide required to produce its effects.

The antagonism of *p*-aminobenzoic acid to the antibacterial action of the sulphonamides is not however entirely specific and can be produced by a wide range of chemical compounds containing a similar nucleus. Procaine and allied substances used for local anaesthesia possess this quality, and this fact must be borne in mind when their use is contemplated during treatment with sulphonamides.

Other substances inhibitory to the action of sulphonamides are known to be present in most body tissues and fluids but the concentration of sulphonamide produced in their therapeutic use can overcome such inhibition. In pus, however, and in necrotic tissues the inhibition of the bacteriostatic action is so marked that it negates any therapeutic usefulness. This restricts very considerably the local use of sulphonamides and their systemic efficacy once suppuration has occurred.

The activity of the different sulphonamide compounds depends on the degree of dissociation of the compounds and thus any apparent differences in activity are quantitative on this basis and not qualitative. Thus the apparent specificity of different compounds in different infections is only related to the fact that the less the susceptibility of the organism the more activity in the compound will be required, though the essential action produced is the same. In addition, other physical attributes may influence the choice of drug. If, for example, a local effect is required in the gut and no systemic action be required it will be advantageous to use a sulphonamide which is not absorbed in any appreciable quantity from the alimentary tract.

With the exception of sulphaguanidine, succinylsulphathiazole and phthalylsulphathiazole absorption from the small intestine is rapid and little of the drug reaches the large intestine. After absorption the sulphonamides are distributed throughout the body uniformly. They enter the body fluids including the cerebrospinal fluid and the secretions in concentrations approximating the blood level. They also pass through the placenta and enter the foetal circulation and are present in the milk of lactating women.

Excretion largely occurs through the kidney. Some of the sulphonamides are excreted to a large extent unchanged, but a proportion, which varies considerably in individual sulphonamides, is acetylated in the liver before excretion. These acetyl compounds are inert therapeutically but assume importance because a number are less soluble than the parent compounds and may crystallise out in their passage through the kidney and produce blockage in the urinary tract. In addition, although possessing no therapeutic action, they retain the toxic properties of the parent compound and in some instances acetylation renders them more toxic. The degree of acetylation of the compound before excretion must also be considered when a local action is required in urinary tract infections for only the proportion of the sulphonamide which is excreted unchanged has therapeutic action locally. Many acetyl compounds are more soluble in an alkaline medium and, in consequence, this mechanism of excretion necessitates an adequate administration of fluids during treatment and also necessitates that the urine be kept alkaline.

The maintenance of constant adequate concentration of sulphonamide completely to prevent the growth of organisms has been shown to be of major importance. If all growth is not prevented early some organisms will continue to multiply and may become resistant even to very high concentrations of the drug. Moreover, such resistance may not be to one compound but may be present to all sulphonamide

rendering further treatment useless. This may be considered from the point of view of the individual patient in whom it occurs but its effect on the population at large is more important, because such resistant bacteria usually retain this character, and are liable to be disseminated, with the result that fresh infections in other individuals are insusceptible to the treatment from the outset.

Penicillin resistance is only a general problem in connection with staphylococci, and here the prevalence of resistant strains is not due to acquisition of this character, but to the breeding out of an originally resistant race which owes this property to forming penicillinase. Resistance to streptomycin can be acquired by any organism very rapidly, and resistant strains of originally sensitive species have become steadily commoner throughout the world since the introduction of this drug. To chloramphenicol and the tetracyclines any organism can develop resistance, but the process is a slower one. Resistance to one of the tetracyclines is usually accompanied by resistance to the others. Erythromycin stands apart and resistance to it is so far rare, but it can be acquired readily and rapidly and will doubtless become a problem wherever the drug is widely used.

The capacity of staphylococci in particular and of various Gram negative bacilli to become resistant to antibiotics which have been in general use for some time is one of the chief incentives in the search for new drugs. Staphylococcal resistance to penicillin and sometimes to all antibiotics except—at present—erythromycin is most frequent in hospitals where cross infection takes place among patients and by way of nasal carriers among the staff. The stage of this process which has been reached in the United States, where the newer drugs have been available far longer than elsewhere, is much more advanced than in this country. It serves as a powerful argument against indiscriminate use. Whenever bacterial resistance is a possibility, laboratory tests should be made to determine which is the most suitable drug to use.

SUPERINFECTIONS

It has long been recognised that during treatment with penicillin the original infecting organism may be replaced at the site of infection by another belonging to a naturally resistant species. More recently, and mainly in consequence of the use of the modern broad spectrum antibiotics, 'superinfections' have been seen to develop not necessarily at the site of infection but in the air passages or alimentary tract, due often to *Candida* (*Monilia*) *albicans*, and sometimes to a staphylococcus resistant both to the antibiotic in use and to others. *Candida albicans* is completely resistant to all antibiotics. These organisms are presumably enabled to proliferate by the elimination of the normal flora of the area, there is some evidence that they may be actually stimulated by the drug. Thrush in the mouth and pruritus ani are common results of *Candida* infection. Staphylococci may cause a severe enteritis and either or both organisms have been known to cause severe and even fatal infection of the bronchi and lungs.

This complication should be watched for, if serious it demands immediate cessation of the treatment producing it. There is no specific treatment for *Candida* infection, staphylococcal infection so caused will usually respond to erythromycin.

LAWRENCE P. GARROD

THE SULPHONAMIDES

INTRODUCTION

The demonstration by Domagk that streptococcal septicæmia could be prevented by the use of sulphonamido-chrysoidin opened a new era in chemotherapy. The activity of this compound was found to be due to the liberation of sulphanilamide in the body.

Sulphanilamide and its derivatives have been widely used therapeutically, and it has been customary to speak of this group of compounds as sulphonamides, and used in this sense it refers to various substituted compounds as well as the parent substance.

Sulphanilamide is the parent substance and the simplest of the group.

Acetylation of the sulphonamido group yields sulphacetamide.

This compound must not be confused with the derivative produced in the body by the acetylation of the *p*-amino group which is therapeutically inert.

Substitution in the sulphonamido group with pyridine, thiazole, pyrimidine, methylpyrimidine and dimethylpyrimidine gives rise to the compounds known as sulphapyridine, sulphathiazole, sulphadiazine, sulphamerazine and sulphadimidine.

compounds. This behaviour can occur in a wide range of organisms which may retain this resistance for a long time.

This phenomenon of resistance is unlikely to occur with short, adequate courses of treatment, but may assume importance during a long course of treatment and especially in relation to efforts at prophylaxis.

THE THERAPEUTIC USE OF SULPHONAMIDES

It is essential for the optimum effect of the sulphonamides that certain principles in their use, and safeguards against ill-effects, should be carefully observed.

In the treatment of infection the concentration of the sulphonamide must be raised to an effective level at the site of infection at the earliest opportunity. The earlier this can be done the better, since sulphonamides are more effective against small rather than large numbers of organisms, and treatment is ineffective if suppuration has occurred. Having attained an effective level, this must be maintained throughout the whole period of treatment. Regular dosage is therefore essential to ensure that the rate of absorption shall be equal to the rate of excretion.

As the rate of excretion of many sulphonamides is relatively rapid, this will necessitate frequent and regular administration of the drugs. Failure to recognise or to observe this necessity may well negate effective control of the infection. The dosage must be regular throughout the 24 hours, even although it may entail waking the patient, for inadequate dosage or inconstancy of adequate concentration not only fail to control the infection, but may encourage the production of resistance in the bacteria to the action of the sulphonamides.

The sulphonamides are given by oral administration unless there is any special contra-indication. They may be given in tablet form or in powder form in water or suspended in milk or with mucilage. Alkali should be given during treatment in sufficient dosage to render the urine alkaline to litmus. Sodium bicarbonate is the best to use for this purpose. Doses of 1 g 4-hourly will usually be sufficient, but must be increased if the urine is not rendered alkaline. The sulphonamides can, if desired, be suspended in the alkaline mixture with mucilage.

If swallowing is impossible the mixtures may be given by nasal catheter or by stomach tube. If this method be also impracticable the sulphonamides may be given intravenously or intramuscularly. For this route the soluble sodium compounds are used.

These sodium compounds are strongly alkaline and will cause considerable necrosis. Intramuscular injection should not be used, therefore, if it can possibly be avoided. In the rare instances, when it is essential, the injection site must be chosen with great care and should be remote from important surrounding structures, especially nerve tissue. Should more than one injection be required the injection sites should be as widely spaced as possible.

The intravenous use of these preparations is safe, provided care is taken to prevent any leakage around the vein, and the injection is given slowly. The solutions should never be given with blood or serum transfusion, since they may cause protein precipitation, but may be given in dilute solution by continuous infusion with saline or glucose saline.

The sodium compounds are totally unsuitable for injection into serous cavities, and should never be used in this way. Injection into the spinal theca will result in disastrous necrosis of the central nervous system.

The use of the sodium compounds either intravenously or intramuscularly should only be undertaken when administration by mouth is impossible. Administration by these routes should never be continued longer than is absolutely essential and the oral administration of suitable sulphonamides commenced as soon as possible.

An adequate response to treatment should occur within 4 days of full dosage. But treatment should always be continued for at least 2 days after the temperature has become normal. Under ordinary circumstances the total length of treatment will not, therefore, exceed 7 days.

Failure to respond within 4 days demands an urgent review of the case, for either the infection is resistant to this form of treatment, and perseverance with such treatment is both useless and dangerous, or the dosage is inadequate and must be corrected rapidly. It must also be recalled that even an organism susceptible to sulphonamide action will be protected from this action in the presence of suppuration.

During the whole of the treatment with sulphonamides it is essential to maintain a high fluid intake. The total fluids must be kept up to at least 3 litres in the 24 hours. This will usually ensure a urinary output of 1,500 ml. Sufficient alkali must be given to render the urine alkaline. These precautions must be taken whenever systemic treatment is undertaken. In some circumstances it is difficult to maintain this high fluid intake. When the intake remains low it is necessary to use the more soluble of the sulphonamide preparations such as sulphacetamide, and in less severe circumstances preparations such as sulphadimidine, the acetyl derivative of which is comparatively soluble and less likely than many others to provoke urinary complications.

Infections of the urinary tract need separate consideration. High concentrations of sulphonamide can be maintained in the urinary tract by low oral dosage, but with a fixed dose of sulphonamide the urinary concentration will obviously vary directly with the urinary volume. In order to produce effective bacteriostasis in the urinary tract an adequate level of sulphonamide must be present constantly in the urine. With diuresis a larger amount of sulphonamide will have to be given to maintain the same concentration of sulphonamide. Since with small or large urinary volume the risk of urinary complication will, of necessity, be the same, since the concentration of sulphonamide is the same, there is no advantage in preserving a diuresis.

The smaller the urinary volume, therefore, the smaller the dose of sulphonamide required. The smaller the dose of sulphonamide, the less the risk of systemic toxic effects, and therefore in the treatment of urinary infections it is advantageous to restrict the fluid intake, so that the dose of sulphonamide can be kept as low as possible.

When renal function is impaired, it may be necessary to maintain a high fluid intake to prevent the onset of renal failure. A higher dose of sulphonamide will have to be given in these circumstances and care observed in the choice of preparation. A more soluble preparation will usually be chosen, so as to obviate any risk of added urinary complication, and if treatment has to be prolonged it must be ascertained that the blood level of the sulphonamide has not risen to an unduly high level.

It has previously been mentioned that sulphonamide bacteriostasis is more easily produced when the concentration of bacteria is small rather than large. It is, therefore, sometimes advantageous in gross urinary infection to increase the urinary volume when using sulphonamides for such cases to reduce the volume concentration of organisms by a diuresis to assist the sulphonamide action.

In all circumstances it is advisable that the urine should be made alkaline. Not only does this render many excretion derivatives more soluble but frequently enhances the bacteriostatic action of the sulphonamides. In a few infections of low sensitivity to sulphonamides the alkali may not enhance the bacteriostasis. Such infections should not now be treated with sulphonamides.

Consideration of all these factors is essential in every urinary infection if good results are to be obtained, and a failure to recognise all the factors involved has resulted in a confusion of multiple régimes and dosage schemes.

Lastly, it should be remembered that the prolonged use of succinylsulphathiazole and allied compounds may inhibit the alimentary biosynthesis of components of the

vitamin B complex and an adequate supply of these vitamins should be ensured during the treatment.

THE TREATMENT OF SPECIFIC INFECTIONS WITH SULPHONAMIDES

THE TREATMENT OF INFECTIONS NOT LIMITED TO THE INTESTINAL OR URINARY TRACT

The scheme of dosage is essentially the same in the treatment of all infections in this group, and the range of dose is dictated by the severity of the infection and the mode of administration by circumstances.

Sulphanilamide and sulphapyridine are not now used, and have been superseded by the more active compounds such as sulphadimidine and sulphadiazine. Although sulphathiazole can be used with good results, the dangers of urinary complications and sensitisation are certainly much higher with this compound and, unless in individual circumstances a specific reason is present for its use, it is better avoided. The doses suggested are for adults of average weight and major deviations from the average will call for modification of the dosage either way.

In severe infections treatment should begin at once with a dose by mouth of 4 g., followed by 2 g. 4-hourly. This dose should be maintained for at least 3 days; after this, if the response has been good, the dose may be decreased to 1 g. 4-hourly, and should be continued until the patient has been afebrile for at least 48 hours. In many cases it is difficult to decide when the dose may be decreased with safety, and provided no signs of intolerance develop and the usual precautions are observed, it is quite safe to continue with the larger dose until treatment is completed. It should be stressed again that a good response should be obtained within 4 days, and the treatment should be completed in a week in uncomplicated cases. Failure to obtain this effect demands a review of the diagnosis and further investigation, as previously described. Should treatment need to be prolonged, it is often possible to maintain an adequate effect after 5 days by reducing the dose to 1 g. 6-hourly.

ages of 1 to 3 years, it is unwise to persist with these dose calculations, and the dose for this age can be calculated as one-third of the adult dose. From the fourth to the tenth year half the adult dose should be given, and from the tenth to the fourteenth year two thirds of the adult dose. After this time adult doses may be used.

The foregoing schemes of treatment are suitable for infections with the hæmolytic streptococcus, with the pneumococcus and with the meningococcus. They are also suitable for systemic treatment used to supplement local measures in wounds and in peritonitis.

In some infections with the hæmolytic streptococcus nephritis may complicate treatment. This complication does not prevent the use of sulphonamides, but great caution should be observed with the dosage and a careful watch kept for toxic manifestations, and it is preferable to use other methods. The blood level should be ascertained and should not be allowed to exceed 10 mg per 100 ml.

Staphylococcal infections, purulent meningitis other than meningococcal, and mixed infections of the lung are unsuitable for treatment with sulphonamides.

Infections with the non-hæmolytic streptococci are rarely susceptible to sulphonamides and treatment with sulphonamides should not be given unless the organism is shown to be sensitive.

Chemotherapy with sulphonamides does not in any way influence the necessity for surgical intervention in the treatment of infection with suppuration, nor should it prevent the administration of antitoxin whenever this is indicated by the variety of infective organism.

THE TREATMENT OF INTESTINAL INFECTIONS WITH SULPHONAMIDES

The sulphonamides which are used for this purpose are sulphaguanidine, succinylsulphathiazole and phthalylsulphathiazole. Sulphaguanidine has been used extensively, but owing to its absorption from the gut in appreciable amounts and the danger of toxic reactions it has largely been superseded by the other two compounds, which are also more active against both coliform and dysentery organisms.

These drugs have been of the greatest use in the treatment of dysentery. Sulphaguanidine should be given in doses of from 3 g to 5 g by mouth, according to the severity of the infection, 6-hourly for 3 days, followed by 3 g twice daily for 4 days. When the dose can be calculated on a weight basis an initial dose of 0.1 g per kg body weight, followed by 0.05 g 4 hourly, should be used until the diarrhoea ceases, followed by 0.05 g 8 hourly until the stools have been normal for 2 days. It is unwise to prolong this treatment for more than 14 days, but the treatment may be repeated after an interval.

Succinylsulphathiazole and phthalylsulphathiazole may be given in similar doses. The dose of the latter compound need not exceed 0.04 g per kg body weight, or 0.02 g when the diarrhoea has ceased. The doses for children can be calculated on the same basis.

Sulphadiazine and allied compounds have also been used for the treatment of dysentery and give good results when used in the dosage recommended for severe infections in the previous chapter. Great caution, however, is necessary in their use to ensure against ill effects after absorption, particularly in relation to renal complications, and the same is true though to a lesser degree in the case of sulphaguanidine. In view of this and the efficacy of succinylsulphathiazole and phthalylsulphathiazole it is recommended that these should be used in preference to other compounds in the treatment of dysentery. When these compounds are used for more than a few days it is wise to ensure an adequate dietary supply of vitamin B. The results of treatment are good and the carrier rate is practically abolished in infections with Shiga and Flexner organisms, but in Sonne infections the results are less satisfactory.

Typhoid and paratyphoid infections and bacterial food poisoning do not respond to this treatment. The results in the treatment of cholera are still inconclusive, and in non-specific gastro-enteritis in children there is little or no benefit. In amœbic dysentery the sulphonamides have been used with benefit, often in association with other forms of therapy, to eliminate secondary infection prior to specific treatment. In non-specific ulcerative colitis the results are disappointing, but sometimes some benefit is produced by their use. When the lesions are in the rectum or lower colon predominantly some benefit may accrue from the use of retention enemata of 7 to 10 g. of succinylsulphathiazole suspended in mucilage, given daily over courses of 10 days. Continuous therapy is inadvisable, but the course may be repeated after an interval.

THE USE OF SULPHONAMIDES IN INFECTIONS OF THE URINARY TRACT

The choice of sulphonamide for the treatment of urinary infection should be determined by ascertaining the sensitivity of the organism if suitable facilities are available for this purpose. But in the interpretation of such information for clinical use the rate of excretion and the degree of acetylation of the compound must be taken into account, so that the actual concentration of the active compound that will be produced in the urinary tract can be assessed.

it would be given 15 or 2 g at a time. It is usual to make the urine alkaline in any treatment with sulphathiazole but the enhancement of bacteriostasis in an alkaline medium with sulphadimidine is not pronounced as with sulphathiazole and the acetyl derivative is not appreciably more soluble, although fortunately the acetyl derivative in this case is readily soluble over the ordinary range of pH and does not present any undue anxiety. Treatment with mixtures of sulphonamides has been advocated in order to spread the excretion time by using compounds of different excretion rates, and also to reduce the risk of urinary complications by diminishing the individual concentrations in order to prevent crystallisation. Such a method carries advantage in theory and provided the dosage be adequate will produce equally good results, though in practice it does not offer any great therapeutic advantage, as a rule, over the use of a single compound.

In some circumstances, particularly when kidney function is impaired, it may be essential to preserve a high urinary volume in order to maintain an adequate renal function. The fluid intake will have to be high enough to ensure a urinary output of not less than 1500 ml per day, a larger systemic dose of sulphonamide will obviously be required if a urinary concentration equivalent to the other methods of treatment is to be obtained, and the sulphonamide should be given in doses as previously recommended for systemic infection of moderate degree. In order to avoid any possible additional urinary complication the more soluble sulphonamides should be used. Sulphadimidine is more suitable for this purpose for it is usually quite free from the risk of such complication, but if the renal impairment is considerable it may be necessary to use a freely soluble compound such as sulphacetamide which carries the advantage of great solubility but is unfortunately less efficacious in producing bacteriostasis and will require a higher concentration. The further management of infection should proceed exactly as described in the other method of treatment.

There are many circumstances in which such treatment may be required prophylactically, or merely to control the degree of infection prior to the use of more active measures to sterilise the urinary tract. Sulphadimidine and sulphacetamide in the way previously described, can be used for this purpose. If, however, such a course is prolonged and there is a known impairment of renal function it is wise to ensure by direct examination of the blood that the concentration of the sulphonamide is not reaching a dangerous level. In most circumstances the concentration should not rise above 10 mg per cent, and above 15 mg per cent is dangerous.

THE COMPLICATIONS OF SULPHONAMIDE THERAPY

During the administration of sulphonamides a number of toxic effects may be encountered. Many of them are of minor importance, and are seen with great frequency and only assume importance if they are unduly distressing to the patient or interfere with adequate dosage. In some cases, however, they may herald some serious manifestation of intolerance or toxicity, and no untoward symptoms or signs should be ignored without due consideration and assessment.

Some clouding or disorientation of mind is frequently encountered, especially with high doses of sulphonamide, and cyanosis with methæmoglobinæmia or sulphæmoglobinæmia is not uncommon. These manifestations are seldom of importance unless extreme in degree, and do not necessitate interference with treatment.

Vomiting and nausea are frequent, more especially with the use of sulphapyridine. They can frequently be overcome by altering the method of administration, and giving a powder suspended in milk or mucilage, or in combination with alkali. If vomiting is difficult to control it is usually worth trying the use of another sulphonamide compound, but administration by parenteral means may be necessary. It

should always be borne in mind that the vomiting may herald more severe toxic reactions.

URINARY COMPLICATIONS

The urinary complications are all related to obstruction in the urinary tract by the deposition of sulphonamides or other derivatives owing to their relative insolubility.

Complete anuria may result if attention is not paid to the fluid intake during treatment, and endeavours are not made to keep the urine alkaline. If these precautions are carefully observed, urinary complications are infrequent. A careful watch should always be kept on the urinary volume and for the appearance of blood, both microscopic and macroscopic, in the urine. Spontaneous complaint of pain in the loins, or even generalised abdominal discomfort, should arouse suspicion.

In the presence of pain, diminished urinary volume or hæmaturia, great caution should be observed, and, unless absolutely essential, the treatment should be stopped. If it is necessary that treatment should continue, generous amounts of fluid must be given, together with alkali, and the urinary volume carefully observed. It is wise, also, if suitable, only to use an easily soluble compound such as sulphacetamide. If, however, oliguria continues, treatment should be stopped. If these measures prove inadequate, and anuria develop, or a marked oliguria persist, ureteral catheterisation should be performed, and irrigation of the ureters and renal pelvis be undertaken. This measure should not be unduly delayed, as it has been shown to be a life-saving measure.

With due precaution, or early treatment, this complication is usually overcome, and no permanent ill effects on the kidney result.

TOXIC EFFECTS IN THE BLOOD

Many patients receiving treatment with sulphonamides show mild degrees of anæmia, which recover spontaneously or with the administration of iron during convalescence. Occasionally severe anæmia is seen with aplasia of the bone marrow, and in some instances severe purpuric manifestations. A rarer, but more disastrous anæmia occurs in the first few days of treatment in association with a severe degree of hæmolytic. More frequent in younger age groups, it appears to be associated with idiosyncrasy to sulphonamide, and is usually exceedingly sudden in its onset. Within a few hours of premonitory headache, severe hæmolytic, at times accompanied by hæmoglobinuria, may appear, followed by fever, jaundice and anæmia.

The white cells may also be affected. Agranulocytosis is a most dangerous complication. It is usually suggested by the onset of fever, headache and soreness or ulceration of the throat, occurring during treatment with sulphonamides. It seldom occurs early in treatment, and is most likely to be seen when treatment is unduly prolonged, thus differing from the effects on the red cells and suggesting that the disease may be brought about by sensitisation to the sulphonamides.

A minor degree of leucopenia is not infrequently seen, but agranulocytosis is not assumed to be present unless the polymorphonuclear count is below 1000 per c.mm., and this investigation is the only certain method of diagnosis. If, however, the white count falls rapidly, treatment should be stopped when the count has reached 4,000 per c.mm., in order to prevent, if possible, the danger of this complication.

The treatment of these toxic effects in the blood is immediate cessation of treatment with sulphonamides and the administration of fresh blood by transfusion. When hæmolytic has occurred, it is wise to keep the urine alkaline and ensure copious urinary output to prevent, if possible, the development of oliguria or anuria from the deposition of blood pigments in the kidney.

DRUG FEVER

Fever is frequently produced by sulphonamide compounds. Most commonly it occurs during the course of treatment, but it may appear during the first day after cessation of treatment. It tends to occur earlier when sulphonamides have been given previously, and is unusual before the eighth day with initial courses of treatment.

Fever is the dominant manifestation, often with rigors, but there may be associated vomiting and even delirium, and occasionally pain and swelling in the joints. Exacerbation of fever during the administration of sulphonamide should arouse the suspicion of this complication, and unless an adequate explanation is forthcoming from the clinical condition of the patient the drug should be stopped. A rapid defervescence usually occurs and no further treatment for this condition is required.

More difficulty is encountered when the fever of the infection passes imperceptibly into drug fever. It should be borne in mind that fever present for more than a week indicates either a failure of treatment or the presence of drug fever. In either case, the treatment should be stopped and the diagnosis will then become apparent.

Fever which recurs after the drug has been stopped for more than 24 hours is almost invariably a recrudescence of infection, and not a result of the therapy with sulphonamide.

CUTANEOUS MANIFESTATIONS

The most common toxic manifestation in the skin is the development of a papular erythematous rash, associated with fever and often vomiting. It most commonly occurs late in a primary treatment, from the seventh to the ninth day, but may occur even within a few hours if sulphonamides have been administered previously. The rash may adopt various patterns, and its distribution is variable, but in all varieties there may be pruritus, often severe. A condition resembling erythema nodosum occurs sometimes from the use of sulphathiazole, and rarely a severe exfoliative dermatitis with any of the sulphonamide drugs. The development of these complications is related to the development of sensitivity to sulphonamides.

Sensitisation can occur both from administration by mouth and by application to the skin, and in both cases seems to be provoked more commonly by sulphathiazole than any other sulphonamide. There appears to be a relationship between the combining of protein and sulphonamide and the development of this phenomenon. The process appears to take about 8 days, and if produced from skin application, induces local eczematous change with a generalised itching eruption, together with fever and malaise. If produced by oral administration, it may be associated with the development of cutaneous lesions, but may not be apparent until sulphonamides are used again.

In either case the condition of sensitivity may last for months or years. It may be specific for an individual compound, but may be a wide group sensitivity. This fact must be borne in mind if administration of sulphonamides is contemplated following their previous use either by mouth or on the skin. It should also limit the use of sulphonamides in treating minor degrees of infection, and application of sulphonamides to the skin should not be undertaken for more than a few days, 5 at the most. Treatment with sulphonamide might be urgently required at a later date, and alarming symptoms may be produced by even a small dose in a sensitive individual, and there is little evidence at present that methods of desensitisation are either safe or successful.

PREVENTION OF COMPLICATIONS

From the preceding description of these complications of the use of sulphonamides, it is clear that a number of these troublesome and often dangerous manifestations

SECTION II

INFECTIOUS DISEASES

A. BACTERIAL DISEASES

THE main results of the invasion and infection of the body by micro-organisms are discussed in the section upon infection and immunity. It is important to distinguish clearly between "invasion", "infection" and "intoxication", and the reader is referred to the section mentioned for the consideration of these several processes.

TOXÆMIA

This term is applied to the condition of a patient who is absorbing into the tissues and circulation toxins elaborated at some local site of microbic infection. The diseases caused by the specific microbes of diphtheria and tetanus are examples of toxæmia, the sites of infection being in the former disease the fauces or larynx or skin, and in the latter disease the damaged tissue about a wound or abrasion. The symptoms of toxæmia are variable, and depend upon the special affinity that the toxins concerned have for certain tissues or organs. There are, therefore, general symptoms common to many microbic infections: fever, rigors, malaise, vomiting, pains in the back and limbs, headache, sweating, etc.; and special symptoms, such as are manifested by an affinity of the toxin for nerve structures (paralyses, spasms, delirium, etc.) or for the heart (arrhythmia, tachycardia, circulatory failure, etc.) and others.

The importance of "focal sepsis" as a cause of toxæmia is hard to assess, but is certainly less than was once believed. In some instances, low fever and vague symptoms of general ill-health are associated with chronic infection of the teeth, tonsils, nasal sinuses or urinary tract, and are relieved when this is effectively treated. The attribution to "focal sepsis" of arthritis, various myalgias and other local disorders remote from the site of the infection rests on less secure ground.

The microbes chiefly concerned in septicæmia are *Staphylococcus pyogenes*, *Streptococcus pyogenes* and the pneumococcus. Much less commonly *N. gonorrhææ*, *H. influenzae*, *N. meningitidis* and *Ps. pyocyanea* perform this rôle.

The local infections tending to lead to septicæmia are chiefly concerned with the throat (streptococcus), the uterus ("puerperal fevers"), the subcutaneous tissues of the hand and foot (infections during operations and post mortem examinations, septic wounds, etc.), and the site of surgical operations (post operative septicæmia).

Symptoms.—The symptoms in septicæmia vary much, there is also great variation in the intensity and course of the disease. Some of the worst cases from the point of view of prognosis are those in which physical signs are conspicuous by their absence, whether as regards the site of the local infection or as regards the development of secondary lesions (thromboses, visceral inflammations, etc.). Thus, in a case of puerperal septicæmia, if a careful examination of the pelvic organs reveals no defect in the uterus or its adnexa, and if no signs of local concentration of the infecting agent be found elsewhere, the case is likely to be one of great anxiety.

It is to be realised that the description which follows is that of a fully developed case, such as was commonly seen before the introduction of chemotherapeutic and antibiotic agents. It happens but seldom now that such treatment is not established early in the disease, with consequent modification of the clinical picture.

The symptoms include pyrexia, usually considerable in degree, and most often intermittent in character. Rigors are not uncommon, though by no means constant. The patient is generally free from pain and local discomforts, but feels exhausted and very ill. The mental state is usually normal, in some cases the outlook is disproportionately optimistic. Sweats are common, especially if the pyrexia is markedly intermittent. Diarrhæa may occur. Some degree of general abdominal distension is common. The spleen may be sufficiently enlarged, yet sometimes too soft, to be palpable. The pulse is quickened, the pulse tension lowered and there may be subjective cardiac disturbances related to the toxic myocarditis which is an invariable result of the main pathological process. A progressive anæmia is one of the most striking features in most septicæmias, both clinically and upon examination of the blood. The leucocytes vary a good deal, and their number constitutes a helpful point in prognosis, the smaller the count the worse the outlook. Loss of weight is not a noticeable symptom, except in cases which become "chronic", nor must the absence of this feature lead, of itself, to a favourable view as to the outlook. Erythematæ are often seen, both diffuse and discrete, especially in cases due to streptococcus infection, they are prone to be evanescent. Purpura is not uncommon. Joint pains and swellings are also common, and though such an arthritis may subside a careful watch must be kept for signs of suppuration. Pleurisy and pericarditis are not infrequent in staphylococcus infection.

Prognosis.—The prognosis is serious in all cases of septicæmia, though less so now than formerly. This is partly because, as the result of the earlier and more extensive use of blood cultures, more cases are recognised, but chiefly because the exploitation of chemotherapy and antibiotics has completely transformed the outlook in many instances of the disease. Of serious import are the following: rigors, the absence of signs of the local infection, the absence of a leucocytosis, rapid progression in the associated anæmia, early dilatation of the heart, vomiting, pleurisy, insomnia and delirium or stupor.

Treatment (see pp 6 and 15)

PYÆMIA

When septicæmia is complicated by the formation of multiple abscesses, or of multiple foci of tissue necrosis, the clinical condition is conveniently spoken of as pyæmia.

can be avoided if care is taken both in the choice of compound and the management of the other features of the individual case. Before deciding to use a sulphonamide it is essential to ascertain whenever possible whether sulphonamides have been given previously, and, if so, what compound has been used, how long it has been used, and in what quantity, and whether the patient experienced any untoward symptoms. To avoid as far as possible manifestations of hypersensitivity, a different compound should be prescribed, but as the sensitivity may not be limited to one compound a small dose of sulphonamide should be given first, if circumstances allow, and the full course should be delayed for 8 to 12 hours, to see if any signs of sensitivity occur. Such precautions may prevent severe reactions.

Whatever sulphonamide is being administered, it is important to ensure that the fluid intake is adequate, so that urinary volume will be at least 1,500 ml. in the 24 hours; and in the case of the sulphonamides, the acetyl derivatives of which are more soluble in an alkaline medium, alkali should be administered.

Finally, watch must be kept each day for early manifestations of toxic reaction, and if treatment has to be prolonged for any reason, a white blood cell count with both total and differential count must be done at least twice weekly after the first week of treatment.

THE USE OF SULPHONAMIDES IN PROPHYLAXIS

In view of the striking results of the use of sulphonamides in the treatment of infection, it is natural that attention should be drawn to the possibility of the prevention of infection by the prophylactic use of such compounds, particularly in a community exposed to infection by an organism known to be sensitive to sulphonamides.

It is clear that the indiscriminate and prolonged administration of these compounds is not without grave risk, but if it should prove possible to overcome an outbreak of infection within a few days, the risks would be no greater than with the therapeutic use of sulphonamides, and such a result would amply justify the risk. For example, the risk would be well justified if infection with the hæmolytic streptococci could be avoided and a relapse of rheumatic fever thus prevented in an individual. To attain this effect, smaller doses of sulphonamide are required than would be necessary to treat an established infection, and there seems little doubt that sensitisation is far more likely with the larger therapeutic doses than the smaller doses required for prophylaxis. It is perhaps in this respect rather easy to over-emphasise the possible dangers of prophylactic doses without due regard to the benefits which may accrue. It must also be remembered that such measures might induce resistance to sulphonamides in various organisms. There is some evidence to suggest that in some epidemics this may have occurred; the risk, however, does not appear at present sufficient to negative further exploration of these prophylactic measures.

The use of sulphonamides in the prophylaxis of gonorrhœa and chancroid has been extensively investigated, and there is no doubt that adequate prophylaxis after exposure to infection will, in the vast majority of cases, prevent the development of the disease; and the result of individual prophylaxis has proved so successful that it has far exceeded the risk entailed, although there is no doubt that in inadequately treated patients the gonococcus may become resistant to sulphonamides.

The results of prophylaxis in rheumatic fever are also encouraging, and there is no doubt that relapses while taking small doses of sulphonamide over a prolonged period are definitely diminished. Although a number of such cases will show some toxic manifestations, the number is surprisingly small, and only in a few cases has it been necessary to discontinue the treatment. The patients, however, must be under careful supervision, especially in the early stages, to watch for the development of

fever or skin rashes, and again during the second to sixth week a careful blood examination will be necessary to avoid the risks of agranulocytosis.

The encouraging results in rheumatic fever led to an investigation of the control of scarlet fever and other infections with the hæmolytic streptococcus. There is a strong suggestion that epidemics of scarlet fever can be brought under control more easily by the widespread prophylactic use of sulphadiazine, particularly in a closed or semi-closed community. The carrier rates, however, for the hæmolytic streptococcus were not diminished, but at the same time there appeared to be a reduction in the number of upper respiratory infections. These experiments have been largely conducted in training camps, and it is not yet certain how valuable such measures will prove for civilian problems.

The development of an outbreak of cerebrospinal fever is always accompanied by a high incidence of carriers of the meningococcus in the naso-pharynx. During the treatment of the established disease it had been noted that the organism disappeared rapidly from this site. The application of this knowledge was exceedingly successful, and by the use of small doses of sulphadiazine for 2 to 3 days an outbreak of cerebrospinal fever abruptly terminated and carriers were virtually eliminated. If, therefore, a case of cerebrospinal fever occurs in a community and the carrier rate is found to be high, the whole community can be treated and the incipient epidemic aborted.

The use of sulphaguanidine and succinylsulphathiazole in the prophylaxis of dysentery, particularly in closed communities, has also been tried. In this disease, as in cerebrospinal fever, the symptomless carrier rate is often high, and this undoubtedly contributes to the spread of infection. Experiments of such prophylaxis have been very encouraging, but knowledge on this point is small at present, and it is unfortunate that the Sonne bacillus is less susceptible to this chemotherapy than other dysentery organisms.

Although the sulphonamides have no effect on virus infections, attempts have been made to prevent secondary bacterial infection occurring during the course of the disease. The results of the prophylactic use of sulphonamides in measles are encouraging, and the incidence of secondary infection is thought to be much diminished.

Prophylaxis with sulphonamides in other diseases is as yet virtually untried, but there is a wide field for possible future use.

E. F. SCOWEN.

All pyæmic patients are septicæmic, but not all septicæmic patients are pyæmic. Some septicæmias tend to be pyæmias from the first, in other cases there is a late development of the pyæmia after a period of simple septicæmia lasting for days or, it may be, weeks. In the great majority of cases of pyæmia the primary infection is obvious.

There are three types of pyæmia according to the anatomical distribution of the primary infection in relation to the circulation.

1 *Systemic venous pyæmia*—This is the form which is seen in osteomyelitis due to *Staphylococcus pyogenes*, in suppurating wounds (*staphylococcus*, *streptococcus*, *Bact. coli*, etc.), in suppurations of the urinary and bronchial tracts, and in suppurating dermatitis and cellulitis. The metastatic abscesses form in the lungs, kidneys, perirenal tissues, joints, bones and, less often, in the heart wall and in the brain. The symptoms are those of a severe septicæmia together with those of the disease processes set up by the focal events just referred to. Some of the cases are of long duration, and when this is so the patient is apt to become very emaciated.

2 *Portal pyæmia* (suppurating pylephlebitis)—This is the form of pyæmia resulting from certain pyogenic infections in the alimentary tract—rectum, colon, appendix, gall bladder and elsewhere. The infection follows in ascending fashion the radicles of the portal vein, setting up a septic thrombosis and ultimately causing multiple abscesses in the liver. The symptoms are those of a severe febrile illness with acute or subacute abdominal signs, moderate jaundice and an enlarging liver. The diagnosis is sometimes difficult, but when indubitable the prognosis is extremely grave. The micro organisms concerned are generally of the coliform group, or *streptococcus*, mixed infection is not uncommon.

3 *Arterial pyæmia*—This form of pyæmia is seen in septic endocarditis. The focus of primary infection, so far as the pyæmic process is concerned, is the endocardium, and especially of the valves, where colonisation of microbes takes place, and whence innumerable septic emboli proceed into the arterial system. Seeing that in the great majority of the cases this focus occurs on the left side of the heart the emboli, if they set up metastatic areas of infection, do so in organs and tissues supplied by the systemic vessels—spleen, brain, kidneys, limbs, etc. In the less common instances, where the endocarditic focus is on the right side of the heart, the infection being grafted upon a congenital lesion, the emboli lodge in the pulmonary vessels, producing multiple infarcts in the lung usually with associated pleurisy.

The microbes most often causing septic endocarditis are organisms of feeble virulence (*streptococci* of the salivary and faecal groups, or *H. influenzae*), this fact accounts for the infrequency of suppuration in the infarcted areas occurring in this disease. When, however, the endocarditis is due to such virulent microbes as *Staph. pyogenes* and *Str. pyogenes*, abscess formation does occur in the infarcts.

Treatment (see pp 6 and 15)

necessary carefully to distinguish between the last two of these relations. The mere isolation of organisms from certain tissues (e.g. the mucoid material of the middle ear) in the post-mortem room does not prove that they were present in these situations during life, still less that they were operative by way of actual infection. It is even doubtful if the cultivation of organisms from the blood of the heart, or from the cerebrospinal fluid, after death, gives evidence of infection during life, though some authorities consider that it does. Much depends, of course, upon the conditions at the time of the investigation.

Terminal infection does certainly occur, however, in well-recognised form and quite distinct from sub-mortem invasion. The organisms most often responsible for the condition are the less virulent strains of streptococci (*Str. viridans* and *faecalis*), the coliform group, staphylococci and the tubercle bacillus. *Proteus* and *Cl. welchii* are also found to operate in this manner at times.

The disease processes in which terminal infection frequently occurs are cirrhosis of the liver, chronic nephritis, diabetes, leukaemia and heart disease. There is a latent form of septic endocarditis (most often streptococcal in origin) which is also of the nature of a terminal infection. Serous membrane tuberculosis, and especially peritonitis, is quite common in cirrhosis of the liver. Many of the patients in whom this terminal infection occurs are so ill at the time the event arrives that it frequently goes undiscovered, partly because their responses to infection are feeble and partly because clinical examination is difficult.

STAPHYLOCOCCAL INFECTION

Staph. pyogenes infection may be either local or general. Local infections are usually cutaneous and include boils, carbuncles, pustular acne, onychia, sycosis, eczema (sometimes), ciliary blepharitis, suppurating sebaceous and Meibomian cysts, suppurating burns, cuts and abrasions. Invasion of mucous surfaces does occur and staphylococci may be responsible for infection of the cranial sinuses (including the middle ear), for some cases of broncho pneumonia and of gastro enteritis (food poisoning). Staphylococci may also be present in the urinary tract, particularly in association with the tubercle bacillus or a stone. General infection, while usually acute or even fulminant, may run quite a chronic course. Pyæmia is prone to occur and the metastatic foci may be single or innumerable. Perinephric inflammation is an important example of the solitary metastasis, in this condition the initial focus may be a trivial skin lesion, healed perhaps for several weeks, the onset is usually abrupt, often with a rigor and pain in the upper part of the loin, some further weeks may elapse before the perirenal swelling becomes palpable. Osteomyelitis and some cases of septic arthritis, particularly of the hip and intervertebral joints, have a similar pathogeny but are wont to be the source of further emboli—in kidneys, lungs, myocardium and brain.

STREPTOCOCCAL INFECTION

The streptococci form a group of micro-organisms in which the different members vary greatly in virulence. They also vary in their morphological and cultural features and in their biochemical reactions. There is, therefore, no little difficulty experienced in any effort at successful classification. Broadly speaking, there are two main groups of the microbe. (1) There is the highly virulent group called *Str. pyogenes*, to which the alternative name *Str. hemolyticus* is applied, on account of its property of hemolysing when cultivated on blood-agar. (2) And there are the less virulent groups, *Str. viridans* and *Str. faecalis*. The first type is usually seen in long and curling chains when recently isolated, and the second is usually seen in short chains of two, four or some number of relatively few members.

Str. pyogenes is the causative microbe in erysipelas, scarlet fever, in acute streptococcal abscess formation, in acute cellulitis and lymphangitis, in severe operation and post-mortem infections when these are of streptococcus origin, and in the more virulent streptococcus infections complicating the puerperium, influenza and some other specific fevers.

Str. viridans is found in association with pyorrhœa alveolaris, with secondary streptococcus infection in rheumatic fever, with arthritis occurring in connection with focal infections and with most chronic and subchronic infections of streptococcal origin. The streptococci found in the heart valves, and in the blood stream in cases of subacute septic endocarditis, are for the most part of this nature.

Str. faecalis occurs in the lower bowel, and is a common cause of urinary tract infections, and an uncommon one of endocarditis.

The clinical results of streptococcus infection vary according as the infection is by the first or by the second of these types of the microbe. In infection by *Str. pyogenes* the disease process is usually acute and often fulminant. Septicæmia results not infrequently, and pyæmia is not uncommon. If endocarditis results from the infection it is acute, and if embolism occurs the infarcts suppurate. In infection by *S. viridans* the disease-process is prone to be chronic, or at most subacute. Septicæmia is uncommon, except in association with endocarditis, in which condition embolic infarcts proceed to coagulative necrosis, but not to abscess formation.

Treatment (see pp 6 and 15)

ERYSIPELAS

Definition—An acute specific disease, due to infection of the skin by *Str. pyogenes*, leading to local dermatitis and constitutional symptoms, of which fever and toxæmia are the most prominent.

Ætiological Factors—Infection by *Str. pyogenes* is certainly the essential factor. The more carefully the cases are examined and the patients questioned the more certain it becomes that in the great majority of them some abrasion, it may be very slight, is present in the skin at the site of infection. This abrasion may be an actual wound, whether of a surgical operation or not. More often it is less apparent—a scratch, an insect bite, the chafing of a foot by a badly fitting shoe, etc. Contact by the human hand during the infliction of these slight injuries is not uncommonly a feature in the case.

Bad hygienic conditions seem to contribute to the incidence of the disease, such as defective sanitation and ventilation in public institutions. Formerly the disease was rife, almost epidemic, in hospitals, and chiefly amongst the surgical patients.

The disease is said to have a seasonal incidence (January to May) and Newsholme showed that the curves of its prevalence conformed somewhat to those of scarlet fever and acute rheumatism.

The disease is more common in women than in men, perhaps because of the puerperal cases.

Symptoms—There is an incubation period of some 2 to 5 days. The onset is usually abrupt, often with a rigor (or a convulsion in little children) and a sharp rise of temperature—102° to 103° F. In severe cases the patient suffers from malaise, aching pains about the body and headache. The headache may be so severe as to mislead the observer into thinking there is some cerebral infection (e.g. meningitis). Delirium may be present, rendering the doubt still greater. If as is sometimes the case the local lesion is not apparent to the patient, or is not discovered on examination, the case may be very obscure indeed. But in the majority of instances there is a feeling of heat, tightness, or pain at the site of infection, leading to the recognition of the dermatitis. The inflammation usually appears during the second day—the skin is red, hot to the hand, slightly raised, with a spreading margin upon which

there may be minute vesicles containing clear or turbid fluid. The area spreads rapidly, and becomes œdematous, the degree of this latter effect varying with the situation of the inflammation. If this is the face, the œdema is marked, especially if the eyelids and lips are involved: the whole face may then be greatly swollen and the patient's features scarcely recognisable. On the limbs there is frequently present some degree of lymphangitis—red streaks, more or less continuous, stretching upwards towards the groin or axilla, in which situations the lymph nodes are frequently swollen, painful and tender. When the dermatitis is fully developed the vesicles already referred to may become blebs of considerable size.

In less severe cases the constitutional disturbance may be much milder, but so long as the diagnosis is definite the development of serious symptoms must always be regarded as possible, especially if the patient be elderly, debilitated or alcoholic.

The course of the disease varies considerably. If uninterrupted by specific treatment it lasts from 1 to 3 weeks. There is a rare type of *recurring erysipelas* in which the same area of skin is involved again and again. One or other of the lower extremities, or the face, is the common site. Though the immediate response to chemotherapy may be satisfactory in this type, drugs do not confer immunity.

Complications.—Albuminuria is not uncommon in all cases in which the temperature is high. Signs of nephritis supervene in not a few severe cases; when this is so the question should arise as to the previous integrity of the kidney. Oedema of the larynx is a rare complication; spread of the inflammation from the face to the orbit is less uncommon, and in this event meningitis is to be feared. Pneumonia sometimes occurs, again in debilitated, elderly or alcoholic subjects. Septicæmia, it may be with a fulminating form of septic endocarditis, is another serious possibility.

Diagnosis.—Reference has already been made to those cases in which the real nature of the disease is masked by the severity of the general invasion symptoms and the non-discovery of the skin lesion. Apart from such instances the diagnosis is rarely difficult if the examination be carefully conducted. The presence of even the smallest vesicle in association with a suspicious red area of skin should be investigated by piercing it with a very fine capillary glass tube and filming and cultivating the contents, even if these seem to the naked eye to be clear fluid. The discovery of a long-chained streptococcus in the films not only establishes the diagnosis, it enables the practitioner to adopt prompt measures of treatment.

Prognosis.—As is the case in all pyogenic infections, the introduction of sulphonamides and penicillin has completely altered the course and outlook of erysipelas. The prognosis, however, remains serious in infants and in old people. It is relatively unfavourable in alcoholics and nephritics. In all others the outlook is good. But septicæmia is of grave omen, and if associated with endocarditis it is frequently fatal. Meningitis, following orbital cellulitis and ophthalmia, is scarcely less lethal. The occurrence of acute nephritis, of cellulitis of the neck or of pneumonia, though all of these give rise to anxiety, does not render the case hopeless.

Treatment.—**PROPHYLACTIC.**—The patient should be isolated, and the greatest care should be taken in nursing, as well as in all the examinations made by the medical attendant. The sick-room should be large and well ventilated.

CURATIVE.—(i) *Local measures.*—Various applications are in use. Perhaps one of the best is ichthammol ointment (25 per cent.), though this has the disadvantage that it somewhat obscures the local signs. A lotion of perchloride of mercury (1 in 4,000), continuously applied on linen strips, is free from this objection. In erysipelas of the face the eyes should be protected by a few drops of mild silver protein (argyrol) (5 per cent.) applied two or three times in the 24 hours.

(ii) *General measures.*—The majority of patients show improvement in both the local and general condition in 24 hours, and there is no need for penicillin. Penicillin is, however, indicated if improvement is not manifest in 24 hours, or if one of the graver complications, e.g. septicæmia or orbital cellulitis is suspect; or if the infection

is complicating chronic nephritis or alcoholism. Full diet is allowed, provided it can be digested.

(iii) *Radiotherapy* has been successfully exploited in the recurrent variety.

SCARLET FEVER

Synonym.—Scarlatina.

Definition.—A specific fever of sudden onset and acute course, characterised by faucial or other local infection by *Streptococcus pyogenes*, a diffuse punctate erythema of the skin, and a tongue at first furred but later raw, with prominent red papillæ. Desquamation follows, and inflammatory sequelæ may occur, involving especially the ears, cervical glands and kidneys.

Ætiology.—Scarlet fever is a disease of temperate climes and seldom gains a foothold in tropical or subtropical countries. It is endemic in large cities and populous centres, tending to flare up every few years in local epidemic form owing to the accumulation of susceptible subjects. Its general epidemic prevalence, however, is irregular, and no definite periodicity has been recognised. In the United Kingdom it is prevalent in the latter part of the summer and reaches its maximum at the end of the autumn; the period of least prevalence being the spring. Of late years, although the incidence has not appreciably declined, the mortality has fallen and the type of case become much less severe. Severity, however, has always varied greatly at different periods and in different regions.

The case mortality of scarlet fever is now not more than 0·5 or 2 per cent. It is greatest in the first year of life and diminishes with age.

Of predisposing causes, childhood and the absence of acquired immunity are the most important. Infants under 1 year of age seldom contract the disease, but mother and new-born infant may share the infection together. The maximum incidence occurs during the fifth and sixth years of life, a period slightly later than in such diseases as whooping-cough and measles. Adults are not exempt, but scarlet fever is rare in the aged. There is a tendency in some families to take the disease in a very severe form. As a rule, one attack protects permanently. Multiple recurrences should probably be attributed to some other cause than scarlet fever.

Poverty, by entailing shortage of food, overcrowding and defective isolation facilitates the spread of the disease and augments its death-rate.

The infective agent resides in the mucous secretions of the nose and throat and in the secondary suppurative lesions. The disease is infectious from its commencement, and the exact duration of infectivity cannot be predicted for any given case. Desquamation is not regarded as dangerous unless the scales are contaminated by the patient's discharges, and the infectivity of urine which remains albuminous has never been proved. The infectivity of scarlet fever is not nearly so great as that of measles, varicella or small-pox.

In most cases infection is by droplets derived directly from a person suffering with, or recently recovered from, the disease, but transmission by infected fomites or infected milk may also occur. Aerial infection by dust is possible, and dust from floors and blankets may possibly be a vehicle. It is an important fact that discharges from the nose, throat and ear may remain infectious for many weeks, and pre-existing purulent discharges also become infectious when scarlet fever is contracted. The occurrence of catarrhal infection of the nose or throat in a scarlet fever convalescent may lead to a recrudescence of infectivity.

Carriers have on occasions spread the disease without themselves showing signs of infection. On rare occasions, too, convalescents, although apparently healthy, have for months remained capable of transmitting the fever. The infectivity of carriers appears to be intermittent, and the receptivity of those exposed is increased by close

and prolonged contact, debilitating circumstances or acute disease, of which diphtheria may be cited as an example. Attendants on scarlet fever cases, although long immune, may finally contract the disease.

Infected milk may be responsible for localised and, sometimes, for more widespread outbreaks of the fever. In most instances the milk has been infected from a human source, in kitchen, dairy or farm, but possible derivation of infection from cows with ulcerated udders and teats is suggested by the well-known Hendon outbreak. Scarlet fever is not known to be transmitted by water or by sewage. Cases of wound infection are not numerous, but puerperal scarlet fever is well recognised.

Pathology.—Klein, in 1887, isolated a streptococcus from the teats and udders of cows at Hendon, and considered it the causal agent in a milk-borne epidemic of scarlet fever. It became customary, however, to regard the streptococci found in the throats and tissues of scarlatinal cases as secondary invaders, it being impossible to grow these organisms from the blood of patients suffering from the fever in its toxic, and presumably uncomplicated form.

Drs George and Gladys Dick, of Chicago, however, in 1923 produced evidence that scarlet fever is a local infection of the throat by a hæmolytic streptococcus, and attributed the general symptoms of the disease to erythrogenic toxins absorbed from the local focus. They infected patients with scarlet fever by swabbing the fauces with a pure culture of this organism and elaborated a test analogous to the Schick test in diphtheria. This is the *Dick test*, made by the intradermic injection of 0.2 ml of a suitable dilution of filtrate of a broth culture in isotonic buffered solution. Boiled filtrate is used as a control. An erythema at the point of injection, maximal in 24 hours, indicates susceptibility to scarlet fever. The same types of reaction occur as in the Schick test (*q.v.*) but in the Dick reaction the erythema is not indurated. During the first days of scarlet fever, unless antitoxin has been administered, a positive result may be expected. A vivid rash may mask a positive test. A few convalescents remain positive to the test, the majority become negative within 2 or 3 weeks. The Dick reaction is almost always negative at birth but the new-born infant of a susceptible mother is usually Dick-positive. It is noteworthy that a large percentage of Dick-positive individuals, although harbouring the bacilli, escape the disease.

In scarlet fever there are, therefore, two components that resulting from the invasive properties of the hæmolytic streptococcus, and that due to absorption of the erythrogenic or Dick exotoxin elaborated by the invading organism. The same strain of streptococcus may cause scarlet fever in one patient and simple tonsillitis in another, because susceptibility to the infection may be associated with immunity to the exotoxin. It is the presence or absence of immunity to the toxin which is revealed by the Dick test. The causal organisms are usually β hæmolytic streptococci of Lancefield's group A, and Griffiths has shown by agglutination that they are members of a group comprising many different serological types.

Susceptible persons can be immunised by subcutaneous injection of increasing doses of scarlatinal toxin at intervals of 7 days. For adults the Dicks advise four or five injections, commencing with 500 "skin test" units and ending with a dose of 50,000, 80,000 or even 120,000 units. The skin test unit of scarlet fever toxin is the smallest amount which gives a standard positive reaction in persons susceptible, and a negative reaction in those immune. The standard reaction is the appearance within 24 hours of an area of erythema not less than 1 cm in diameter. If too large an initial dose of immunising toxin is given, a transitory "miniature scarlet fever" may result, and rheumatism may be activated, but this is rare. The simultaneous injection of 2 or 3 minims of 1:1000 adrenaline chloride solution prevents serious reactions. Immunity develops more slowly than in diphtheria, and its duration is indefinite but prolonged. If the Dick test proves positive 6 months after, a further injection is recommended in the case of those nursing scarlet fever.

By immunising horses, an antitoxic serum is produced, which will bring about a

rapid amelioration of the toxic symptoms of scarlet fever, but has little influence in preventing complications.

Schultz and Charlton pointed out that intradermic injection of 1 ml. of the serum from a patient convalescent from scarlet fever will, in a few hours, cause a local blanching of the rash of the fever. This is known as *the blanching test*. W. Mair suggests that the test is due to antitoxic immunity in the donor, which will account for its occasional failure, and also the fact that the serum of some donors not known to have had scarlet fever, will give the reaction. Scarlet fever antitoxin has the same blanching property, and is now used for the test.

The post-mortem appearances in scarlet fever are not distinctive. The rash, unless hemorrhagic, disappears after death. Such gross changes as are found in the fauces, cervical glands, lungs, heart, kidneys and liver, together with moderate enlargement of the spleen and lymphoid structures, merely indicate an acute infective process. In severely toxic cases, early decomposition with much post-mortem staining of the tissues, fluidity of the blood and subserous ecchymoses, indicate the intensity but not the identity of the infection. In cases surviving longer, inflammations of the lungs, serous sacs, endocardium, pericardium and joints may be present, and desquamation may be recognised. Scarlatinal nephritis is acute (type I) nephritis.

Symptoms.—The incubation is short, the period between infection and the first symptoms being from 2 to 4 days, with an average of 72 hours. The rash appears 4 days after infection.

Invasion is abrupt, the cardinal symptoms being vomiting, headache and sore throat. In some severe cases vomiting may be so urgent as to suggest irritant poisoning, especially if accompanied by diarrhoea; in mild cases vomiting may be absent. Rigor is uncommon, convulsions occasionally occur in children. Cough and catarrhal symptoms are decidedly rare, but a mild conjunctival injection is not unknown. The skin is hot and dry, the cheeks are flushed and the eyes bright. The limbs ache, the appetite is in abeyance and the tongue rapidly becomes coated with white fur, through which the papillae project as red points (*strawberry tongue*). Slight nocturnal delirium is common. The temperature rises rapidly, and even on the first day may reach 103° or 104° F. An undue acceleration of the pulse is usually a marked characteristic of sharp infections, rates of 160 or more being common in young children, and rates of 120 to 140 in adults.

Very mild attacks often occur, and in these the symptoms of invasion may be absent, the rash being the first indication of the disease.

Inflammatory redness of the tonsils, fauces and uvula is present in the early stages of the disease. Later, this becomes more vivid, the tonsils are swollen and a distinct follicular exudate often appears; oedema of the fauces soon makes its appearance in severe cases, and may be accompanied by free mucous secretion. The tonsils may become covered by a thin necrotic film, or a more or less coherent exudate may form which encroaches on the faucial pillars and base of the uvula, and closely simulates the membranous exudate of diphtheria. In the more severe forms of scarlet fever, the tonsillar and faucial inflammation is very intense, and both ulceration and sloughing occasionally occur; thick muco-pus trickles down from the naso-pharynx, the nasal sinuses are invaded and acid discharge blocks the nostrils and excoriates the upper lip. The respiratory obstruction is especially severe if adenoids are present. In such severe cases, inhalation broncho-pneumonia is a decided danger.

A punctate injection may often be seen on the soft palate and adjacent part of the roof of the mouth even before the appearance of rash on the skin, and is diagnostic. The skin eruption usually appears within 24 hours of the invasion, but may be delayed, sometimes for several days. It appears first on the upper part of the chest, the root of the neck and the upper arms as a finely punctate erythema; sometimes it is first seen in the axillae. It quickly spreads over the trunk and limbs, reaching the legs last. The cheeks are merely flushed, and the existence of an area of circum-oral pallor is a

well known and striking feature. The thick skin of the palms and soles is also in most instances free from the distinctive rash. The eruption shows a symmetrical intensification in certain regions, such as the lower abdomen and groins, the inner aspects of the thighs, the axillæ, the back, and the points and flexures of the elbows and knees. Pressure produces a transient blanching.

Of the two elements of the rash, one is minutely punctate, the other erythematous. It is the former which gives it its distinctive character. On coarse skin the puncta are particularly large. When the erythematous element is intense the skin may actually appear œdematous and the puncta be quite obscured. In such cases, on subsidence of the rash, yellow staining may be apparent. In addition to punctuation and erythema, minute petechiæ or small linear hæmorrhages are sometimes seen in the flexures of the elbows (*Pastia's sign*), groins, wrists and knees. By application of a tourniquet to the upper arm petechiæ may be rapidly produced at the flexure of the elbow. This is the *Rumpel Leede phenomenon*. It may also be positive in measles, small-pox, typhus, purpuric states and peliosis rheumatica. The linear hæmorrhages in the flexures remain when the rash has faded, and together with coarse injected papules on the outer sides of the arms and legs afford valuable diagnostic evidence. The rash on the buttocks and extremities may assume a slightly blotchy papular appearance, and so bear a distant resemblance to that of measles. Minute sudamina sometimes accompany the rash, giving rise to the variety known as *scarlatina miliaris*. Itching is not common, and urticaria is rare, but in some cases accompanies or precedes the outbreak of the rash.

The rash may be quite transitory or may last a week or even longer. Generally speaking, it is more pronounced in severe attacks, but sometimes attacks which are quite mild show rashes of considerable intensity and persistence. A dusky, blotchy, morbilliform eruption, generally limited to the convexity of the knees and elbows, but sometimes more widespread, may supervene in grave cases. It is known as the *septic rash*.

At the time of the initial faucial inflammation the lymph glands at the angles of the lower jaw are swollen and tender. During the eruptive period a moderate enlargement of the axillary and inguinal glands, sometimes of the posterior cervical glands as well, is often to be detected. The spleen is rarely to be felt. At times the glandular swelling leads to confusion with rubella, but the glands do not attain the size or show the marked localisation and tenderness characteristic of this disease.

In an average case a rapid rise of temperature marks the invasion, but the maximum may not be attained until the full development of the rash on the third or fourth evening, when readings of 103°, 104° or even 105° F may be registered. Slight morning remissions occur. The fall is by lysis, reaching the normal by the fifth or sixth day of the disease. Termination by crisis is unusual. In bad cases of a septic type, the fever is prolonged, with increasing daily oscillations as septicæmic symptoms become prominent. In the malignant or toxæmic type of the disease, the fever is higher from the first and shows less remission, but occasionally is ominously subnormal throughout. A protracted remittent fever may occur in scarlet fever without local symptoms or complications to account for it, this variety is sometimes known as the "typhoid type." It is septicæmic in origin.

Abrupt rises of temperature during the convalescent period may signalise the onset of such complications as adenitis, otitis, nephritis, endocarditis, empyema or a metastatic abscess. Sometimes such pyrexial attacks occur without ascertainable cause, but a thorough examination of the patient is always necessary. Very mild cases of scarlet fever without obvious febrile disturbance certainly exist.

Desquamation is characteristic, but the degree to which it occurs is very variable. The tongue peels in patches or strips, and by the fourth day is raw with prominent papillæ (*raspberry tongue*). The flushed cheeks begin to shed a fine powder during the febrile period. Fine peeling of the lobules of the ears, of the margins of the lips and of the skin at the root of the neck, possibly also above the pubes, next makes its

appearance By the end of the first week peeling is generally well marked on the neck, chest, inner sides of the arms and possibly on the trunk Within a fortnight it may be seen on the hands and possibly on the feet It may not be complete on the latter until over 6 weeks from the onset of the fever Partial redescamation often occurs on the soles and is not infectious The characteristic of the desquamation is the pinhole or ringed form in which it commences, the horny layers of the skin being shed first over the summits of the papillæ, forming apertures which enlarge centrifugally and fuse with their neighbours Where the skin is thick, as on the hands, and feet it tends to separate in larger flakes, or may even be thrown off in the form of incomplete casts A characteristic form of peeling is sometimes seen on the fingertips when separation begins, as a split parallel to the free edge of the nail

In severe cases considerable loss of hair may accompany or follow desquamation but is temporary only, at all events in the younger patients Furrows may also appear across the nails and take several weeks to reach the free edge

Although desquamation typically proceeds as described above, there are cases of true scarlet fever where it is insignificant. It is unsafe to pronounce definitely against scarlet fever on this ground until 3 weeks have elapsed In doubtful cases the hands and feet should be watched with care A change to negative in the Dick test is confirmatory A dry powdery appearance of the palms and soles is sometimes the sole indication of peeling During desquamation the skin may appear harsh, dry, cracked or even eczematous

A polymorphonuclear leucocytosis makes its appearance shortly after infection and reaches a maximum with the full development of the rash It persists a variable time In severely toxic cases it may fail to appear A unique feature in favourable cases is an increasing eosinophilia during convalescence this may even reach 10 per cent.

VARIETIES—These are (a) Simple or Benign, (b) Septic or Anginous, (c) Toxic Malignant and (d) Hæmorrhagic. Surgical or wound scarlet fever and scarlet fever occurring during pregnancy or the puerperium, also have their special features

Simple scarlet fever is characterised by an onset of moderate severity in which the initial vomiting is not repeated and sometimes is absent The faucial inflammation is slight, and the temperature which may reach 102°F has almost reached its acme in 24 hours, generally the climax is reached by the third day and amelioration of symptoms is then rapid The urine may be normal throughout, or a trace of albumin may accompany the febrile disturbance By the third or fourth day the tongue, at first slightly coated, has peeled, and slight powdering may be evident on the cheeks Convalescence is rapid.

The *septic or anginous* variety comprises most of the severe and fatal cases It is characterised by intense faucial inflammation and a tendency to the development of septicæmic manifestations Repeated vomiting sharp diarrhoea and prostration may signalise the onset The faucial inflammation is either severe from the first or unexpectedly becomes so after a lapse of 2 or 3 days The tonsils are much swollen and a patchy or coherent membranous exudate may form Rapid and destructive ulceration of the tonsils, soft palate and its pillars sometimes occurs The mucous membrane of the mouth may be excoriated and bleed at the slightest touch The pharynx and even the upper aperture of the larynx, may become involved in the inflammation, although as a rule implication of the latter is more suggestive of diphtheria than of scarlet fever The discharges from the throat excoriate the angles of the mouth and a purulent acid rhinorrhoea irritates the nares and upper lip Deglutition is painful respiration is obstructed, and the patient often sleepless restless and later delirious The cervical lymph glands become swollen and tender, and peri adenitis or extensive sloughy cellulitis of the neck may ensue This sometimes gives rise to fatal hæmorrhage by eroding large veins or even an artery Cyanosis and coldness of the extremities and cardiac dilatation are common The rash is generally intense, dusky and blotchy The temperature often reaches 104° or 105°F

in the early stages of the disease, and pyrexia may persist long beyond the ordinary period and, changing its type, assume a remittent or intermittent septicæmic form.

Death may occur in the first week, more often life is prolonged into the second week, by which time circulatory failure becomes pronounced and hypostatic congestion of the lungs or spreading broncho pneumonia occurs. Otitis, arthritis, suppurations of the serous sacs, endocarditis or nephritis may appear as complications, and a true scarlatinal pyæmia be evident.

Many patients show septic symptoms of a much milder type and make good recoveries. In grave cases which recover, improvement is very gradual and usually sets in towards the end of the second week, but may be later.

Toxic or malignant scarlet fever is characterised by a toxæmic condition out of all proportion to the degree of inflammatory reaction in the throat. Such cases are marked by high fever, cerebral disturbance, profound prostration and grave circulatory failure. The rash is often petechial, but in the most severe attacks the patient may die before it has time to appear, and the real nature of the disease may only be revealed by the supervention of scarlet fever in contacts. The throat may be intensely injected, but the œdema, ulceration and thick, purulent secretion which characterise the septic variety may be absent altogether. Sometimes convulsions precede death, but mostly delirium merges into coma. Rarely, however, the patient dies of circulatory failure with vomiting, prostration and extreme pallor, but with clear intellect, suggestive of the type of death seen in some cases of diphtheria.

Sufferers from the malignant type of scarlet fever mostly succumb within a week of the onset, sometimes within 24 hours. But, as in the septic form, cases of the toxic or malignant type are not now so common or characterised by such extreme malignancy as formerly.

Hæmorrhagic scarlet fever—Rarely scarlet fever assumes a purpuric form, with bleeding into the skin and sometimes from the mucous membranes also. This complication may make its appearance towards the end of the second or during the third week, and often proves fatal. It is possible that some of the cases formerly described as scarlatinal, where hæmorrhages occurred earlier in the eruptive stage of the disease, were really hæmorrhagic small-pox, with prodromal rashes of scarlatiniform character.

Surgical scarlet fever may be a sequel of operations, wounds or burns and scalds. It is often seen after operations on the nose and throat. The incubation period is short, often less than 3 days, and the rash may make its first appearance around the site of trauma. Faucial inflammation save in throat infections is often slight, and although the exanthema is present, faucial swabs may be negative. The infected wounds show a great tendency to suppurate. When the infection starts from a wound or abrasion on a limb, injected lymphatic vessels are often evident which show a characteristic punctate rash along their course. The corresponding lymph glands are enlarged and tender. The infected lesion may be small and is often overlooked, but the discovery of lymphangitis in a scarlet fever patient should always arouse suspicion that the infection is of this type. When the fever follows burns or scalds the incubation period is also short and the accompanying angina may be slight. Cases of surgical and of burn scarlet fever where the throat is not primarily involved are not highly infectious. They are often left in general wards with impunity, but there is no doubt that occasionally they spread the infection.

Scarlet fever may arise in the pregnant woman. In early pregnancy it is rare, and is said not to lead to abortion, but occurring later it is very prone to produce abortion or premature delivery. When the infection occurs either immediately before or immediately after labour, it is apt to assume a grave form with a very high mortality from septicæmia, but mild attacks may occur even at this period.

Anomalous forms of scarlet fever occur in which one or more of the cardinal symptoms are lacking. In some only sore throat is recognised (*Scarlatina sine eruptione*) and yet the patient may transmit the typical disease. The cases of infec-

tious sore throat which often herald outbreaks of scarlet fever belong to this category. In these patients there is immunity to the erythrogenic toxins but antibacterial immunity is lacking. In others the rash is so ephemeral or atypical that its true nature escapes recognition. In yet others, the rash is the most pronounced feature, both fever and sore throat being insignificant. In cases where the rash is very scanty or insignificant and also after antitoxin treatment, desquamation may not be at all marked.

Complications—These fall into two groups—those which arise locally in connection with the faucial and naso-pharyngeal inflammation, and those of a general or more remote character. To the first group, in order of frequency, belong otitis, cervical adenitis, rhinitis, secondary tonsillitis and stomatitis, and aspiration bronchopneumonia. The second group includes rheumatism, albuminuria, nephritis, endocarditis, inflammations of the serous sacs and metastatic abscesses. In severe infections complications show a great tendency to occur in combination rather than singly.

Otitis—This is met with in from 10 to 15 per cent of the cases, and is an inflammation of the whole mucous tract of the middle ear. Its greatest frequency is in childhood, and its incidence is favoured by the presence of adenoids. It is more common in severe attacks, and may show itself by the end of the first week of the fever or later. It is often bilateral. Earache with an injected and bulging tympanic membrane are the signs to be expected, but sometimes a free discharge of muco-pus or pus and blood from the ear is the first indication. Unexplained pyrexia not due to fresh faucial or glandular extensions or to one of the distant complications should always lead to a careful examination of the ears. Perforation generally occurs in the upper part of the tympanic membrane. Deafness may occur, but fortunately is transient in most cases. Pain and tenderness with slight oedema of the mastoid appear in some instances, and may be accompanied by restlessness, vomiting and fluctuating temperature. The intensity of these mastoid symptoms may vary from day to day. In children the mastoid air cells are very superficial, and pus easily makes its way beneath the covering periosteum.

Rarely the labyrinth becomes implicated. In such cases sudden deafness, vomiting, vertigo and nystagmus may occur. Labyrinthine deafness may be permanent.

Such intracranial complications as meningitis, extradural abscess, lateral sinus thrombosis, cerebellar or temporo sphenoidal abscess, belong to the more chronic forms of ear disease, but occasionally they arise during the acute stage. Persistence of mastoid tenderness with local headache and slight fever may be the only signs of smouldering inflammatory mischief invading the dura in the vicinity of the lateral sinus.

In most instances scarlatinal otitis subsides in a few weeks, the perforation of the membrane closes and hearing returns.

Secondary adenitis—A considerable swelling of the upper cervical lymph glands may suddenly occur during the convalescent stage of the fever. The swollen glands are usually those behind the angle of the mandible or higher up under the insertion of the sterno-mastoid muscle. The adenitis, the basis of which is a congestive oedema with reticulo endothelial proliferation, generally supervenes during the second, third or fourth week of the disease. It is marked by local tenderness and a sharp accession of fever. In favourable cases the temperature becomes normal in a day or two and the glandular swelling rapidly subsides, but suppuration may ensue.

Secondary tonsillitis should suggest the possibility of diphtheritic infection. Peritonsillar abscess may occur. Ulcerative stomatitis with much fetor of breath and sometimes even sloughing of soft tissues and necrosis of bone are also looked upon as secondary infections. Vincent's organisms, amongst others, should be sought for in such cases.

Rhinitis—Acrid or purulent rhinorrhœa is characteristic of septic attacks. The air sinuses may become infected. A rhinorrhœa which occurs in the later stages of the fever is often responsible for the transmission of scarlatinal or diphtheritic infection. True diphtheria bacilli are more frequently found in the nasal than in the ear discharges.

Nephritis.—Slight albuminuria during the eruptive stage of scarlet fever is transitory and of no great importance, but about the third week nephritis may supervene. Its incidence has fallen progressively during the past 50 years in part because of the increasing mildness of scarlet fever and in part, perhaps, on account of the use of antitoxin. Formerly between 4 and 7 per cent., the case incidence is now under 0·5 per cent. It is more common in severe than in mild attacks. Chill, damp and exposure favour its incidence. The onset may be insidious or fulminant. In the insidious cases albuminuria, at first slight, and even intermittent, is the first sign. In the fulminant cases, headache, vomiting, pyrexia and even rigor may mark the onset. The urine becomes heavily loaded with albumin, casts and blood, and there is more or less suppression. The temperature may rise gradually or suddenly and show marked daily remissions. Lumbar pain is uncommon, but abdominal pain and constipation are marked features of some attacks. The amount of dropsy is very variable; it may be considerable in ambulant cases. Anæmia is of rapid onset and very pronounced. The blood pressure is raised. In a favourable case some improvement occurs within a week, the secretion of urine increasing, but the hæmaturia and albuminuria take much longer to clear up. In some cases albuminuria persists and chronic nephritis may ensue. The duration of an average attack may be put at 7 weeks, but is subject to much variation. Broncho-pneumonia, pulmonary œdema, œdema of the glottis and uræmic symptoms occur in severe cases. Convulsions may be recovered from, but coma is of bad augury.

In the septic type of scarlet fever sharp hæmaturia with casts and streptococci may accompany other pyæmic manifestations. This is embolic in origin.

Rheumatism.—This is common, and usually makes its appearance towards the end of the first week. The arthritis is fleeting and mostly involves the hands and wrists. Joint effusions are not always present. The temperature is raised. Sometimes the endocardium and pericardium are implicated, as in ordinary rheumatism, but the profuse sweats and creamy tongue are absent. Scarlatinal rheumatism is more common in adolescents and adults than in children. A history of previous rheumatism is often obtained.

A mono-articular or multiple suppurative arthritis with, it may be, other pyæmic manifestations is sometimes seen and is generally of later onset.

Cardiac complications.—There are three groups: those due to toxæmia; those secondary to rheumatic or pyæmic complications; and those accompanying nephritis. The toxæmic effects are cardiac dilatation and acceleration of the pulse, which are so characteristic of this fever.

Scarlatinal rheumatism is occasionally the precursor of simple or more rarely of malignant endocarditis. The influence of nephritis in producing hypertension has already been mentioned. Pericarditis may occur quite early in some cases of the septic type. The effusion is generally purulent.

Pulmonary complications.—Neither bronchitis nor broncho-pneumonia is common, but aspiration broncho-pneumonia may complicate septic cases. Oedema of lungs may arise during the course of acute nephritis. Lateral sinus thrombosis may give rise to pyæmic infarction of the lungs, empyema and even pneumothorax. A primary empyema, often of insidious onset, occurs in some patients. Pneumonia is rare; occurring early in the disease, it is streptococcal in nature and the prognosis is very grave. Streptococcal peritonitis is a very rare sequel of scarlet fever.

Nervous complications.—If the delirium of onset, the nervous manifestations of nephritis and the cerebral complications of otitis are excluded, it may be said that nervous disturbance during the course of scarlet fever is rare. In those predisposed, epileptic fits may signalise the invasion. Hemiplegia with convulsive onset, incomplete paraplegia and peripheral neuritis have all been described, but hemiplegia is more often secondary to nephritis or to a cardiac lesion than primary. Chorea develops occasionally, usually in association with arthritis and endocarditis. Tetany some-

times occurs. Mental disturbance of a maniacal or melancholic type is an infrequent sequel, or may show itself during the acute stages.

On rare occasions *gangrene* of the extremities has been encountered. It is sometimes embolic in origin and leads to mummification, but gangrene has more frequently been described in association with purpura and sometimes with congenital syphilis.

Post-scarlatinal diphtheria was, in pre-antitoxin days, one of the gravest complications. Diphtheria may develop at the onset of the fever, but more often appears during early convalescence, frequently and deceptively as a rhinitis. It occurs more often in hospital-treated cases than in others. Every throat or nose inflammation about the nature of which there is the slightest doubt should be subjected to bacteriological examination at once. This is a more rational procedure than the indiscriminate injection of all scarlatinal patients with diphtheria antitoxin. All ear discharges should also be bacteriologically examined.

Relapse and reinfection.—A recurrence of the fever and rash before complete recovery from the initial attack occurs in from 0.5 to 7 per cent. of those treated in hospital. In such cases it is usual for the original infection to be replaced and protracted by one of different serological type.

Diagnosis.—Detection of β hæmolytic streptococci in the nose or throat suggests scarlet fever and their absence the reverse. A positive Dick test before the third day of the attack is in favour of scarlet fever (it should become negative later) but a negative result does not exclude it. A positive Schultz-Charlton blanching test, made by the intradermic injection of 0.2 ml. of a 1 in 10 dilution of immunised horse serum applied to the newly developed rash, preferably on the lower abdomen, is of more value. The reaction takes 8 hours to develop, and attains a diameter of 3 cm. or more. Its value in the diagnosis of doubtful cases with ill-developed or fading rashes is small.

The chief diagnostic difficulty arises with mild attacks and with patients who come under observation after the initial stage. In the former the rash is evanescent, constitutional disturbance slight and the tongue often atypical. A history of a previous attack is of great weight for exclusion, but diagnosis can only be confirmed by the supervention of desquamation or of some characteristic complication. Sometimes the infection of a contact gives the clue. In days immediately following the rash significant signs are: slight staining of the trunk, faint striae in the flexures of the elbows, knees and groins, or a triangular patch of fading punctate erythema over Scarpa's triangle. The submandibular glands may be enlarged, and coarse papules resembling goose-skin present on the outer aspects of the arms and legs. The tongue has usually peeled by the fourth day and remains raw and papillated for about a week. Slight albuminuria, in the absence of diphtheria, is significant.

Desquamation of the typical pinhole type rarely occurs in other conditions than scarlet fever; the character of the accompanying symptoms and the time of appearance of the peeling must be taken into consideration.

Simple tonsillitis is distinguished by the absence of punctate rash, a tongue which does not peel but remains heavily coated and absence of desquamation elsewhere. But a simple erythema may be present, with fleeting muscular pains and sometimes otitis, and even endocarditis or nephritis may occur as complications.

Careful scrutiny of the body for a rash will usually prevent confusion with *diphtheria*. When faucial exudate is present in scarlet fever, it is usually softer and less coherent than in diphtheria, and any subjacent grey ulcerated areas are depressed below the general surface. In scarlet fever, too, the faucial pillars and palate may show the punctate rash, whilst pallor of the throat is more distinctive of diphtheria. In scarlet fever, febrile disturbance is more marked, initial vomiting is common and delirium may occur. The fugitive erythema which sometimes appears on the chest in diphtheria is not punctate. Bacteriological examination is decisive in diphtheria, but the two diseases may coexist.

When *influenza* is rife, cases of scarlet fever are apt to be overlooked, but in influenza rashes are exceptional, and careful observation of the progress of the disease will soon lead to a correct diagnosis.

Lobar pneumonia may, in children especially, by its abrupt onset, high fever, vomiting and faucial inflammation, give rise to suspicion of scarlet fever, a suspicion favoured by the flushed face and circumoral pallor which may be present. But the throat affection is trivial, the respirations are rapid and accompanied by action of the *alæ nasi*, and there is no punctate rash on the chest. Sooner or later consolidation of the lung may be detected, often in such obscure cases at the apex or high in the axilla.

Food, drug, serum and enema rashes often cause difficulty. Of drugs the most important rash-producers are copaiba and similar oleo-resins, quinine, phenazone, the salicylates, aspirin and belladonna. Arsphenamine compounds, gold salts and sulphonamides may also do so. Anomalous distribution or polymorphic character of the rash should at once arouse suspicion, especially so the discovery of urticarial wheals. Fever, slight generalised adenitis, enlargement of the spleen and leucopenia are recognised accompaniments of some drug rashes.

Erythema scarlatiniforme is characterised by a punctate eruption which is sometimes patchy and confined to the trunk. The rash is remarkably persistent, and desquamation may ensue whilst it is still in the florid stage. The peeling is profuse and the subjacent skin often erythematous. The characteristic sequelæ of scarlet fever are wanting. The disease is not known to be infectious and is very apt to recur, which gives a clue to its recognition. *Acute exfoliative dermatitis* is by some regarded as identical.

German measles in the scarlatiniform stage closely resembles scarlet fever. The diagnosis turns on the trivial character of the accompanying symptoms, which are chiefly catarrhal, and the tender swelling of the posterior cervical, mastoid and occipital glands. Even when the rash is scarlatiniform on the trunk, distinct morbilliform elements may often be recognised about the wrists and on the lower extremities, and this, with the history of an initial spotty rash on the face and around the mouth, is of great significance. The eyes are suffused and subsequent desquamation is insignificant. Sequelæ are practically unknown.

Measles is more easily distinguished. The rash is different and invades the face. Catarrhal symptoms are pronounced and Koplik's spots are present. Difficulty is only likely to arise in those cases of scarlet fever where a blotchy rash is present, or where the appearance of a septic rash may simulate intercurrent measles.

Prodromal rashes of a scarlatiniform type may appear in small-pox, chicken-pox and measles. In small pox, the petechial rash is usually confined to the bathing-drawers area and to the axillæ. Sore throat is in favour of scarlet fever, whilst rigor and severe lumbar pain suggest small pox. The eruption of the latter disease appears on the third day, and a doubtful case should always be isolated over that period. The initial rashes of small-pox are said to be absent in children under 10 years of age.

The eruption of chicken-pox may be heralded by a rash which is scarlatiniform, but it is more likely to be erythematous. The diagnosis turns on the condition of the fauces and tongue, the absence of other signs of scarlet fever and the speedy appearance of vesicles on the palate and the trunk.

As a prodromal rash in measles, a scarlatiniform eruption is rare. The catarrhal symptoms which accompany it will arouse suspicion, which is confirmed by the discovery of buccal inflammation and Koplik's spots.

Prognosis—The mortality of scarlet fever varies with the type of the prevailing epidemic. Of late years, in Great Britain, a mortality of less than 1 per cent has been the rule. Of other factors, age is the most important, the mortality being greatest in infancy, diminishing rapidly after the second year, and continuing to fall as puberty is reached, the least fatal period being from puberty to 36, after which age a slight rise occurs. The death-rate is slightly higher in males than in females. Tuberculous

infections are apt to be lighted up, and puerperal patients run a grave risk of septicaemia. Chronic renal disease is likely to be adversely influenced.

Malignant attacks are often fatal, and the septic type of attack is also serious, especially if broncho-pneumonia supervenes. In adults, sleeplessness and delirium are unfavourable signs, and in children, convulsions occurring after the initial stage. Nephritis in many instances clears up, especially if detected early and properly treated. Grave symptoms are coma, repeated vomiting and suppression of urine. Oedema of lungs often precedes the fatal issue. Haemorrhagic scarlet fever, fortunately rare, may be rapidly fatal. Perhaps one case in every three recovers.

Of other complications, pericarditis is the worst. It is often purulent and may be associated with empyema. Early pneumonia is rare but often fatal. Hemiplegia, if of vascular origin, mostly becomes permanent. The danger in otitis media is remote rather than immediate.

Treatment.—PROPHYLACTIC.—Infectivity ceases mostly within a period of 4 to 6 weeks, but is apt to be prolonged in the presence of complications. A negative throat culture does not always indicate cessation of infectivity, and this test is not employed as a routine measure. Late desquamation of the hands and feet is not a source of infection, but discharges from the nose, throat or ear are dangerous.

Convalescent carriers are responsible for something less than 3 per cent. of the cases treated in fever hospitals. They are often characterised by unhealthy conditions of the nose, throat or ear, discharges from which may have reappeared. Patients with persistent tonsillitis, adenitis, rhinorrhœa or otitis should be isolated for at least 12 weeks from the commencement of the fever.

The discharge of patients direct from wards containing others in the acute stage of the disease should be avoided; isolation for a few days in a separate apartment is advisable. It is safer to remove those who remain Dick-positive during convalescence from all contact with acute cases. In cold weather the practice of bathing on the very day of discharge is not advisable, as a catarrh may be thus induced. Patients should not pass straight from isolation into the company of children and other sus-

being maintained at 55° to 60° F. Overalls should be worn by attendants, and all articles used by the patient sterilised at once.

The action of the skin is promoted by a daily wash and a tepid sponge every evening during the pyrexial stage. This may be replaced by a daily warm bath when defervescence is complete. The bed coverings should be adequate, but not too heavy. During the febrile stage the diet should consist of milk, barley water and weak tea. Water and fruit juices may be given freely, to counteract dehydration. A full diet may be given directly the tonsillitis allows the patient to swallow without discomfort. In the absence of complications there is no need for the patient to be confined to bed for more than a week.

Attention should be paid to the mouth, teeth and gums, since oral sepsis is believed to bring its own train of local complications. The bowels should be regulated with mild aperients.

The sulphonamides and penicillin are of great value in controlling the local lesion, penicillin is to be preferred and should be administered in the doses recommended on page 8. These drugs, however, have no influence upon the rash and do not counteract the effects of circulating toxin. The routine use of antitoxin is no longer advocated and it should be reserved for the now rare severe cases. Reactions are often marked and the intramuscular route is advisable, 20,000 to 40,000 units may be injected depending upon the gravity of the infection. Preliminary desensitisation is essential in sensitised patients (see p. 4). A unit is the amount of antitoxin which neutralises 50 skin test doses of the standard scarlet fever toxin.

Pyrexia, with restlessness, insomnia and delirium, may be controlled by tepid sponging and acetylsalicylic acid or paraldehyde. A cold pack at 60° or 70° F. for 15 or 20 minutes is beneficial when nervous symptoms are pronounced. After the middle of the second week, if albuminuria is present, cold sponging and cold packing should be avoided.

Persistent vomiting may be controlled by the use of diluted or citrated milk or temporary substitution of albumin water. *Liquor iodi mitis* in doses of 3 or 5 minims in water is often efficacious. When swallowing is painful the feeds should be small and often repeated.

For the local treatment of the throat and nose, gargles are quite ineffective. Ointment should be applied to the nares and upper lip to prevent excoriations.

Local septic complications should be treated with antibiotics or chemotherapy. Cervical adenitis is treated by smearing glycerin on the neck and applying cotton wool. Poulting appears to precipitate suppuration. Inflamed glands should only be incised when the presence of pus is certain. Care should be taken that the ears are clean. The pain of otitis may be mitigated by the application of hot, dry cotton wool, or a rubber hot-water bottle. Incision of the tympanic membrane is rarely necessary when chemotherapy is started early. Discharging ears should be cleansed frequently with hydrogen peroxide and mopped dry with spirit but never plugged. After the fourth week of the fever, removal of adenoids and infected tonsils shortens the duration of discharge. Watch must be kept for mastoid tenderness and oedema. If there is persistent mastoid tenderness or pulsating purulent aural discharge in spite of chemotherapy, mastoidectomy is required.

Scarlatinal rheumatism is usually mild and transitory, salicylates, or acetylsalicylic acid give relief. When joint swellings persist, a mild pyæmic condition is often present, and may be associated with endocarditis. Some advise a cautious trial of intravenous scarlatinal serum in such cases, but the use of sulphonamides or penicillin is more rational. When the presence of pyæmic arthritis is suspected an exploratory aspiration under strict asepsis may be advisable. This may lead to subsidence.

Scarlatinal nephritis—The importance of daily examination of the urine and avoidance of chill must be emphasised. No patient with albuminuria should be allowed up and, if nephritis sets in, prolonged rest in bed is more than ever essential.

The incidence is said to be less in patients treated with penicillin. Treatment is thus advocated for acute nephritis, described on p. 1119.

Grave circulatory failure calls for strict recumbency and oxygen inhalations.

The most promising treatment for *hæmorrhagic scarlet fever* is blood transfusion.

RHEUMATIC FEVER

Definition—An acute disease, characterised by fever, arthritis and a special tendency to carditis.

Ætiology and Pathology.—An association of rheumatic fever with hæmolytic streptococci of Lancefield's Group A has long been recognised and is firmly established. The history in many cases is of an upper respiratory infection followed, after a latent period of 2 to 3 weeks, by the onset of rheumatic fever. Years of patient investigation have failed to prove the disease immediately attributable to invasion of the tissues by these streptococci, blood cultures are uniformly negative and in fatal cases no bacteria can be recovered from the diseased organs. The problem of the relation between the hæmolytic streptococcus and the lesions of rheumatic fever remains. The explanation most favoured at the present time is that the disease process is a manifestation of bacterial allergy (see p. 5). The toxic products of streptococcal infection are the allergens in the view of the protagonists of this hypothesis, who cite the resemblances between rheumatic inflammation and the allergic tissue response of animals injected with foreign proteins in their support.

While most workers regard rheumatic fever as a consequence of hæmolytic streptococcal infection and as an example of specific bacterial allergy, this belief has not gone unchallenged. Although serological evidence of infection, such as positive precipitin and complement fixation reactions and raised titres for antistreptolysin-O and antistreptin, is usually to be found, it is not invariable. It has been suggested that the rheumatic process is usually set in motion by a streptococcal infection, but that its effect is not a specific one and that other influences, such as trauma, cold, damp and fatigue may initiate attacks. Those who hold such views regard rheumatic fever as a non specific allergic reaction or possibly as a response to an increasing titre of auto antibodies against some constituent of connective tissue.

It is possible that susceptibility is hereditary and claims have been made that it is transmitted as a single autosomal recessive character. There is, however, general agreement that rheumatic fever is more common in the presence of poverty, overcrowding, malnutrition and damp, and it is difficult to separate the effects of these environmental factors from hereditary predisposition.

Rheumatic fever is rare before the age of 4 years or after the age of 30 years, the curve of incidence shows a peak at 7 years. There is a particular tendency to recurrent attacks. Little racial predisposition is to be noted and, although flord rheumatic fever is rare in tropical countries, rheumatic heart disease is common. In Great Britain autumn provides more attacks than any other season of the year.

MORBID ANATOMY—The characteristic pathological lesion of rheumatic fever is the Aschoff node. It is usually fusiform in shape, consisting of a central area of necrosis with a number of epithelioid cells arranged fan wise and a surrounding halo of lymphocytes. The nodule is later replaced by fibrous tissue.

Rheumatic fever is an affection of connective tissue and its lesions are scattered throughout the body, the most frequent sites are the heart, joints, subcutaneous tissues, arteries and serous membranes. Inflammatory reactions occur in systemic, pulmonary and cerebral arteries, they are marked by lymphocytic infiltrations with proliferative changes in the arterial linings which may obliterate small vessels. Pulmonary consolidation of a curious rubbery consistence is not uncommon in fatal cases, but its specific rheumatic character has been called in question.

The heart bears the brunt of the affection in fatal cases, Aschoff bodies are

always found in the myocardium, disposed around vessels, and often associated with a diffuse myocarditis. Lesions occur along the line of closure of the valves. Swelling and necrosis of the fibrillæ are followed by fibrous depositions which later become organised to form the familiar verrucous vegetations and finally, undergoing thickening and fibrosis, lead to the valvular defects of chronic rheumatic heart disease.

Symptoms.—In adults the onset often following 2 or 3 weeks after a streptococcal infection of the naso-pharynx, is usually abrupt, with the sense of chill, accompanied almost at once by pains in a joint, the knees and ankles being the commonest. The characteristic clinical picture is of a fugitive polyarthritis, the acute inflammatory changes in one joint fitting overnight to light upon another, leaving the first apparently normal. Knees, ankles, wrists and shoulders are affected in this order of frequency. The number of joints affected and the severity of the inflammation vary greatly, at its worst there is swelling, redness with intense pain and a rapidly appearing effusion. Less commonly the joint disease affects several joints simultaneously and in children small joints may show changes. It is not rare in the adult for the arthritis to be strictly monarticular, usually limited to one knee, and for the migratory tendency to be lacking. Articular function suffers no permanent impairment and is soon restored to normal.

The temperature may reach, but seldom exceeds, 102° F unless a complication such as pericarditis be present, the fever remits, or even intermits, so that the chart shows an "irregular" curve. The pyrexia is peculiarly sensitive both to exacerbations in the disease (which are common), to relapses (which are also common) and to complications. Sweating is generally profuse, the sweat being of a peculiar "acid" smell. The urine is scanty and high coloured, and if the fever is marked there is usually a trace of albumin present. As in most acute fevers, the secretions of the mouth and alimentary tract are lessened, leading to a heavily coated tongue, anorexia and constipation.

The heart is affected to a variable degree by rheumatic inflammation in at least 75 per cent. of cases of rheumatic fever. Definite evidence of carditis in the presence of active rheumatism is provided by (1) the development of a blowing pan systolic murmur at the apex or a short mid diastolic apical murmur indicating mitral valvulitis, (2) the development of a mid-systolic murmur at the base or an early diastolic murmur in the left parasternal region indicating aortic valvulitis, (3) a rough to-and-fro murmur over the præcordium indicating pericarditis (together with electrocardiographic changes), (4) outward displacement of the apex beat due to cardiac dilatation. Slight shifts in the position of the apex are difficult to evaluate and gross degrees are associated with other signs of carditis, (5) the appearance of signs of heart failure, (6) the development of conduction defects or other arrhythmias confirmed by changes in the electrocardiogram. Gallop rhythm is not reliable and difficult to interpret as most normal children have a third heart sound and tachycardia due to fever often produces a summation gallop.

The blood shows a considerable leucocytosis (15,000 to 30,000) and an anæmia which is a constant feature of the disease and quickly reveals itself in the patient's facies. The erythrocyte sedimentation rate is increased during the active stages of the disease, in the acute phase Westergren's method may give readings of 100 mm or even higher in the first hour.

Electrocardiograms show pathological alterations in the great majority of cases if tracings are repeated sufficiently frequently. The PR interval will frequently exceed 0.21 seconds, abnormal T waves and evidence of intraventricular block may occur. A prolonged QT interval is common during the active phase.

ABERRANT TYPES—*Subacute* attacks are common, especially in children (see p 51) and in old rheumatic subjects. Their importance lies in the fact that all the time the heart may be suffering damage. Although this is less common in adults than in children, arthritic signs may be absent in cases of rheumatic endocarditis, as in rheumatic pericarditis.

Complications—As already stated, at least one half of all cases develop some heart lesion. We have spoken of *myocarditis* and of *acute endocarditis*, and of the advent of the latter, should it arrive, about the end of the first week. The endocarditis is generally a valvulitis, most often mitral, less often aortic, but in some cases both mitral and aortic. *Pericarditis* is less common, though it may be the only manifestation of rheumatic infection, and pericardial effusion, especially of the massive sort, is nowadays quite uncommon.

Skin eruptions, though a specific feature of the infection, are not very common, except in children. The profuse sweating quite often leads to *sudamina*, and these, becoming inflamed, lead to *miliaria*. True *rheumatic erythematata* are much more common in the subacute cases than in the acute ones. *Purpuric* eruptions, again, are more often seen in aberrant types of the disease.

The only *pulmonary complication* of any consequence is pleurisy, and this is by no means common if we preserve the usual strict criteria of physical signs for its recognition and omit "*pleurodynia*", in which condition the pain is more often intercostal than pleural. Indeed it may be said that, in the absence of pericarditis and of severe endocarditis, rheumatic pleurisy is rare. Pneumonia also is unusual, but there is a condition of the lung in severe rheumatic fever, again when complicated by grave endocardial, pericardial and pleural affections, which simulates it somewhat, the lung tissue is in a mixed state of congestion, collapse and oedema. A thin serous pleural exudate often accompanies this condition of the lung, and, no doubt, because of the associated pericarditis, it is more often found on the left than on the right side. Rheumatic *peritonitis* has been described in children.

Hyperpyrexia was formerly a much dreaded, and not very uncommon, complication. It is now of extreme rarity. The condition arises suddenly in most cases, though in a few there is a suspicious prodromal amelioration in the pain, sweating and general discomfort. The temperature rises rapidly to 106°, and unless checked by cold applications it may quickly reach 109° or 110° F. Before this stage is reached the patient has become tremulous and excited, then delirious and then semi comatose, with a dusky lividity of the face and a failing pulse. Most of such cases are fatal. If prompt treatment succeeds in lowering the pyrexia it may need to be resorted to again in a few minutes or hours, since recurrence of the condition is to be expected.

Course—The course of rheumatic fever is variable and unpredictable. Monocyclic, polycyclic and continuous forms have been described, but a more useful classification is into (a) those in which the active process rapidly subsides and the patient recovers without cardiac damage or with only a minimal valvular defect, (b) cases in which the process remains active for months or years with frequent recrudescences and rapidly advancing disability, (c) rapidly progressive cases terminating fatally in a few weeks or months.

Variations from these three categories are common. Recurrence is frequent, being estimated at 25 per cent. in patients between 4 and 13 years, but only 8.5 per cent. in patients between 14 and 16 years.

Activity of the disease process is judged by the presence of fever, arthritis, rheumatic nodules, tachycardia, leucocytosis, a raised erythrocyte sedimentation rate and transient electrocardiographic changes.

Convalescence is often tedious, and the resultant anemia and heart weakness warn the careful practitioner not to attempt to hurry it. Rheumatic fever patients are as liable to *relapses* as they are to recrudescences, and it is no uncommon thing to see a patient slip again into almost as bad a state as he originally was, including, it may be, painful swelling of the very same joints as were first affected. The great danger of these relapses lies in the risk of heart inflammations arising during the subsequent attacks when perchance the patient escaped them at the first.

Prognosis—Recovery is the rule in this disease, death during a first attack is very uncommon. When death occurs there is invariably serious carditis, especially

the converse error arise. But the disease-process is nearly always much more severe, the temperature being much higher and showing greater oscillations. The painful part is generally the lower end of the femur or tibia, and careful examination reveals it to be epiphyseal rather than arthritic. As in pyæmia, to which type of infection the disease really belongs, blood cultures are usually positive (*Staphylococcus aureus*).

(3) *Gonorrhæal arthritis* is not usually so acute a disease, nor is the patient often so ill as in rheumatic fever. The affected joints are fewer in number, and, as in pyæmia, the course of the individual involvement is much longer. The inflammation, too, affects periarticular as well as articular structures, not seldom it involves adjacent tendon sheaths also. Gonococci may be isolated from the joint effusions. Although the presence of a urethral or vaginal discharge makes a diagnosis of gonorrhæal arthritis likely it does not prove it; and it must be remembered that the discharge not infrequently ceases temporarily with the onset of the arthritis.

(4) *Gout*, when present in the acute arthritic form, may be mistaken for rheumatic fever; rarely does the converse happen. The patient is generally a man over 40 years of age, the number of joints involved is rarely more than two, the skin over these is generally dusky red in hue, and shining, there is often definite soft œdema. The presence of severe pain when the affected joints are at rest is much in favour of gout. The degree of fever is usually much less in proportion to the degree of joint inflammation than is the case in rheumatic fever. The presence of tophi may be taken as confirmatory of gout in a doubtful case.

(5) *Reiter's syndrome* is distinguished by the history of conjunctivitis and urethritis, the arthritis is seldom fugitive and frequently affects simultaneously two or more joints. Fever seldom exceeds 100°F and there is no improvement with administration of salicylates.

Treatment.—(1) *General*—With as much promptness as possible, the patient is put to bed, and is kept there until it is certain that the inflammatory process has ceased to be active. To gauge activity of the rheumatic infection both clinical and pathological observations are needed. If the obvious features of acute rheumatism, such as fever, sweating, arthritis and subcutaneous nodules are absent, if the position of the apex beat remains constant, if the pulse frequency during sleep is normal, and if anæmia, leucocytosis and the raised erythrocyte sedimentation rate have disappeared then the infective process may reasonably be considered at an end.

The bed should be chosen carefully, narrow enough to admit of easy nursing, and having a soft but firm mattress. The patient lies in blankets with a long flannel garment opening down the front, and having sleeves to the wrists, this garment is changed as frequently as need be, according to the degree of sweating. The position of the patient is one of recumbency, with the affected joints supported in a position of maximum comfort. Movements of the limbs are generally best carried out by the patient's own efforts, and in all except severe cases, movements of the body as a whole may also well be left to the patient. During the acute febrile period the diet should be light and an abundance of fluids permitted. Once the fever is under control the quantity may be increased so that a high caloric value is maintained but care should be taken that it remains easily digestible.

Sodium salicylate is generally held to be a specific remedy. It controls the arthritis and causes the fever to decline. The erythrocyte sedimentation rate reaches normal levels more rapidly and there is general belief, but no convincing proof, that recurrences are fewer and health is regained more quickly when patients are treated with this drug. It should be given in sufficient quantities, and the doses should be distributed as evenly throughout the 24 hours as is compatible with securing good sleep for the patient. At the onset of treatment of an acute case in an adult, gr 20 should be given every 2 hours during the day, and every 4 hours during the night (gr 200 in the 24 hours). Many authorities advise that twice this amount of sodium bicarbonate be added to the salicylate to prevent acidosis, the effect of the sodium bicar-

bonate is apparently to diminish the quantity of salicylate circulating in the blood and the combination is probably best avoided unless vomiting makes it imperative. As the fever and pain diminish these quantities may be given somewhat less frequently, a note being kept on the temperature chart of the total amount given in the 24 hours. In a child of 12 years or so, half these quantities may be given. If no amelioration follows these doses in 48 hours they should be increased by 50 per cent. (gr. 150 in 24 hours). If an exacerbation occurs, or a relapse threatens, after the dosage has been reduced, it should be at once adjusted to its original level. The drug is not unpleasant to take, and its taste is easily masked by liquorice water as a vehicle. Quite apart from the inestimable value of giving adequate doses so as to gain time, there is an additional value in this procedure from the point of view of diagnosis, for a patient suffering from acute arthritis with fever, who is not considerably better after 48 hours' treatment by full doses of salicylates almost certainly is not suffering from rheumatic fever. The diagnosis in these circumstances should be at once revised. It will be found that the great majority of patients tolerate the above specified doses of salicylates without ill-effects. In the few instances in which it produces vomiting, or intense depression, or delirium, or coma, or hæmaturia—symptoms thought from time to time to be toxic effects of the drug—either aspirin or salicin may be substituted. But care must be taken in deciding that such symptoms are really due to the salicylate and are not manifestations of the rheumatic poison. Modern synthetic preparations of sodium salicylate are fairly free from the contaminations which were formerly rather common. In the early stage of the disease it may be necessary to adopt more rapid palliative measures for the *severe pain*, especially if this prevents sleep. Nothing is better than opium, either as pulv. ipecac. et opii, gr. 10, or pil. saponis co., gr. 5. It is better to avoid phenazone and phenacetin. The treatment of heart complications is discussed elsewhere. Against the occurrence of these complications, apart from the value of early and liberal use of salicylates, we seem to be powerless.

Hyperpyrexia is met by prompt application of the cold pack; the pack may need frequent renewal, and in extreme cases the water used for it must be iced. The most constant vigilance is necessary in such cases, which, as already stated, are happily rare nowadays.

(2) *Local*.—The position of optimum comfort of the affected joints has been already referred to. The use of splints for fixing the joints often gives relief. In the milder cases it suffices to wrap the joints in cotton-wool and bandage them lightly. In the more severe cases a lotion of tinct. opii, 1 fl. oz.; glycerin, 2 fl. oz.; water, 12 fl. oz.; sod. carb. to saturation, used hot, gives as much relief as anything. An alternative is one of the preparations of methyl salicylate, used freely, but without rubbing. Aspiration of the effusion is scarcely ever needed; its indication, indeed, should raise doubts as to the diagnosis.

(3) *During convalescence*.—Convalescence is generally slow, and should not be hurried. If the heart has suffered by direct inflammation, the recumbent position must be prolonged until it is certain that quiescence is established in that respect; this usually means from 4 to 6 weeks after the subsidence of the fever. The transition from strict recumbency to a sitting posture should occupy a whole week, by the gradual addition of pillows, and the further return to ordinary active life should be graduated with care.

(4) *Preventive treatment*.—The prophylactic value of tonsillectomy has been found to be disappointingly slight, but it is justifiable in patients with recurrent tonsillitis or unassailable evidence of chronic tonsillar infection. At least 2 months should elapse between the disappearance of all sign of rheumatic activity and performance of the operation.

It has been demonstrated that recurrence and recrudescence are much less likely to occur in the absence of infection of the upper respiratory tract. To this end 0.5 g.

of a sulphonamide daily has been given by mouth for a prolonged period. Prevention is also possible by means of long-acting penicillin preparations: a dose of 1,200,000 units of benzathine penicillin can be given intramuscularly at intervals of 1 month.

CEREBROSPINAL FEVER

Synonyms.—The name here chosen seems least open to objection. "Cerebrospinal meningitis" is the best alternative, but cerebrospinal meningitis may be caused by micro-organisms other than the meningococcus, and meningitis may not be present at all, or may not constitute the chief lesion, in some cases of meningococcus infection. "Epidemic cerebrospinal meningitis" is much less desirable, because it suggests that there is an essential difference between the epidemic and the sporadic cases of meningococcus infection, which difference does not in fact exist. "Meningococcus infection" brings the various pathogenic possibilities of the micro-organism into line with those of the pneumococcus, with which it has close analogies, but the term does not connote a disease. Meningococcal fever, as suggested by Banks, is an acceptable alternative.

Definition.—A specific disease, due to infection of the body by the meningococcus, occurring both in epidemic and in sporadic form, and most often manifesting itself as an acute meningitis tending to involve the whole cerebrospinal axis.

Epidemics of cerebrospinal fever are marked by several features peculiar to the disease, offering a striking contrast with other epidemic diseases. For a long time these features were very difficult of explanation, until the existence of "carriers" became recognised, and supplied the solution to much of the epidemiological problem. Amongst these curious features may be mentioned the erratic nature of the outbreaks, the inability to trace the connection between one epidemic and another, the relative or even total escape of certain localities close to others in which the disease was rife, and the small proportion of persons affected in any one district. In closed communities, such as camps, and especially in times of war, the disease finds a fertile soil. When the "carrier rate" rises above 20 per cent. an epidemic is likely to ensue.

On clinical, bacteriological and epidemiological grounds there is no distinction to be drawn between sporadic and epidemic cases of cerebrospinal fever. But it is not entirely by means of the sporadic cases that the infecting agent persists, but by "carriers" also. There is little doubt, however, that from the sporadic cases, as from a smouldering infection, new epidemics light up. The present conception of the disease, from an epidemiological point of view, is that of a very widespread infection, with a total morbidity that is very low, but with foci of more intense virulence here and there. These foci of more intense virulence appear and disappear, being preceded and followed by a somewhat higher level of permanent incidence in the districts concerned.

Ætiology.—The geographical distribution of the disease is very wide—world-wide, in fact.

Cerebrospinal fever is a disease of winter and spring. This seasonal incidence is borne out by all observers, and is a very important feature of the disease. It compares markedly with the seasonal incidence of poliomyelitis epidemics, which are at their height in the summer months.

In civilians about half the cases occur below the age of 5 years and 65 per cent. below 10 years; after the age of 25 years cases are uncommon. During the war-time epidemics a special risk is run by young men in the Armed Forces and the age-incidence is considerably higher.

Direct case-to-case infection is uncommon, and there is seldom more than one case in a household; thus infectivity must be low. Infection is conveyed by droplets, and the conditions which favour its spread are overcrowding and inadequate ventilation; upper respiratory tract infections which cause sneezing and coughing; and an increase in the carrier rate.

THE MENINGOCOCCUS.—The meningococcus (*Neisseria meningitidis*) is rather smaller than *N. catarrhalis* and larger than the gonococcus—the other two pathogenic diplococci which are Gram-negative in staining reaction. It is a strict aerobe, and requires the addition of some animal protein or of legumin to ordinary culture media to ensure growth. After cultivation for three or four generations it will grow on ordinary agar, but sub-cultures die rather suddenly. Optimum growth takes place at 36° to 37° C., and growth ceases at 42° C. and at 25° C. Vitality is low, especially to drying; sunlight kills in less than 12 hours.

Types of the Meningococcus.—By employing the agglutination test, controlled by the absorption test, M. H. Gordon (1918) differentiated four separate types of meningococci occurring in the cerebrospinal fluid of actual cases. His classification has now been abandoned in favour of two broad serological groups. Group I, containing Gordon's types 1 and 3 is responsible for 95 per cent. of epidemic cases; Group II strains predominate in sporadic cases.

As the result of this research during the War of 1914–1918, specific type immune sera were introduced which markedly lowered the mortality of the disease. They have now been superseded by chemotherapy.

The primary habitat of the meningococcus, both in actual cases of the disease and in "carriers", is the upper part of the naso-pharynx and the posterior nares.

Symptoms and Course.—Cerebrospinal fever is protean in its features and especially in its modes of onset. Out of the large number of different manifestations that occur, certain cases repeat themselves with sufficient constancy to constitute clinical "types", capable of description and of recognition. Cerebrospinal fever is a disease the course of which has been changed by the application of chemotherapy. Much of the clinical description which here follows is concerned with the unmodified infection. Chemotherapy has cut short the disease process and has largely abolished the severe complications.

1. THE ORDINARY OR ACUTE TYPE.—The incubation period is difficult to estimate with accuracy; there are reasons for considering it to be 4 or 5 days. The illness begins with the usual symptoms of an acute specific fever, and for the first day or two, or for longer than this if the possibility of the disease under consideration is not borne in mind so as to lead to a special examination, there may be nothing to distinguish the illness from one or other of several acute febrile infections.

The onset is usually sudden, with fever, headache, general malaise and vomiting. The temperature usually rises rapidly and attains a fairly high degree on the first day (102° to 104° F.).

The headache is usually intense, is often referred to the occiput, and shows little or no response to the customary palliative drugs given to relieve it.

There is frequently a rigor in the adult, or a convulsion in the infant or child. Vomiting is more often met with in children than in infants, and is quite common in young adults.

In addition to the three cardinal symptoms at the onset—headache, fever and vomiting—the following are quite common, but are not nearly so constant: delirium, pains in the neck and limbs, and some degree of catarrh either of the nose, naso-pharynx, conjunctiva or ear. In some cases there is considerable bronchial catarrh and in others definite enteritis. In addition to the pains referred to the limbs there may be pain and swelling of the joints.

After some 2 to 4 days of these initial symptoms, evidence of meningeal irritation begins to show itself in more or fewer of the following developments. The vomiting is repeated, despite the fact that the invasion symptoms are past. The pulse is irregular in rhythm, and in older children and in adults it is often relatively infrequent when compared with the height of the temperature. The respirations are irregular. The vasomotor system is unstable, leading to periodic flushing of the face and to the

presence of *tâches cérébrales*. The patient lies on his side with legs drawn up and prefers the shelter of the bed-clothes. The pupils are dilated and the light reflex is sluggish. There is photophobia, with intolerance of noise and of all kinds of interference. Examination of the neck reveals a stiffness of the muscles, which cannot be overcome without pain. The hamstrings are found to be taut, so that the knees cannot readily be extended if the hips are flexed (Kernig's sign). The abdomen is retracted and the superficial reflexes are abolished. The mental state is one of restlessness and mild delirium with troublesome insomnia. The headache may become quite intolerable and may require morphine for its reduction. In a considerable number of cases a rash appears during the first week—either a number of large rose spots about the trunk and limbs, or a macular eruption like that of measles or a few small petechiæ scattered over the trunk, neck and extremities. Herpes is common, and is generally situated at the usual places—the angle of the mouth, the chin and the nose. There is a leucocytosis of considerable degree (20,000 to 40,000).

Towards the end of the first week the mental state changes to a condition which may perhaps best be described as one of resistant stupor: the patient can be roused by an effort at examination, or by a change of position; but either proceeding is resented, and he quickly resumes his huddled posture. The headache is less constantly severe, but shows sudden and marked exacerbations, often nocturnal, with complete insomnia. The neck rigidity increases, and the head is retracted. The back also becomes stiff. Flesh is lost rapidly. Polyuria is common, with polydipsia. The temperature generally remains fairly high, and, although this is by no means invariable, the fever approximates to the continued type.

Assuming that the course of the disease is not interrupted by lumbar puncture or by specific therapy, the condition of the patient remains much the same during the second, and perhaps during the third, week of the illness. But the wasting continues. The temperature often becomes intermittent in type. One of the three modes of termination will be followed.

(a) *Recovery*.—This is gradual when it occurs, and is often interrupted by sudden recrudescences, throwing the patient back into a state which leads to renewed anxiety. The temperature chart is often interrupted in its defervescence by sudden rises, with or without a corresponding recrudescence of the meningitic symptoms. Ultimately the fever completely subsides, the patient ceases losing flesh, the headache and stupor pass off and the rigidities slowly disappear. The pulse-rate remains high for some time in a good number of cases, and some authors regard this as a sign that the patient is not yet free from the possibility of relapse, and therefore as an indication for caution in treatment. The actual stage of convalescence, once it is established is rarely interrupted. If the temperature and pulse-rate have remained normal for 14 days, the risk of relapse may be considered to be passed. It may be some weeks, however,

succumbs to the disease, or, if he eventually survives its ravages, it is to be left with mental defect, deafness, blindness, hemiplegia or diplegia

Opinions differ as to the frequency of true relapses in cerebrospinal fever. This is probably due to the fact that what some authorities term relapses others consider to be merely recrudescences. It is certain that the latter are very common, indeed, they are a characteristic feature of the disease.

2 THE SUPERACUTE TYPE—This form of the disease is common at the height of an epidemic. The invasion symptoms are abrupt, and the patient is from the first very ill. Delirium is marked, with most tiresome insomnia, and the headache may drive the patient to a state of acute mania. The temperature is usually very high (104° to 106° F), and intermits. Skin eruptions are more constantly present than in the ordinary type, but are by no means necessarily petechial in character. Discharges are apt to occur from the nose and conjunctival sac. The tongue is dry and tremulous. The meningococcus can generally be grown from the blood by culture, and has even been demonstrated in cover-slip preparations made from the blood direct. The leucocytosis is high (30,000 to 40,000). After 3 or 4 days the active mental state changes to stupor, if the cerebral pressure is not now relieved by lumbar puncture this stupor passes into coma. Even if the pressure is relieved by this procedure there is a great tendency for the patient to slip back into a comatose state, then, with pulse, respirations and temperature all rising, with insensitive pupils and absence of corneal reflex, the surface of the body becomes livid, the lungs congested and death occurs.

3 THE FULMINATING OR MALIGNANT TYPE—This form is prone to occur during the evolution of an epidemic. But it is by no means rare as a sporadic manifestation of the disease. It is more often seen in older children, adolescents and adults than in infants and younger children. The abrupt appearance of fever, headache and active delirium, rapidly passing into coma, and the whole course of the disease may not exceed 12 hours.

In all fulminating cases of cerebrospinal fever there is a rapid development of septicæmia. In some of them the septicæmia covers the whole of the disease, symptoms of meningitis being absent, and the meninges being free from gross lesions on examination post mortem. The patient is most often a child, exhibiting petechæ and signs of circulatory failure—a small frequent pulse, extremities cold and livid, respiration rapid and shallow. A hæmorrhagic suprarenal lesion is often present (Friderichsen-Waterhouse syndrome). Even more constantly than in the superacute type is a blood culture positive, but the course of the disease is too rapid to admit of a diagnosis by this method during life.

4 MILD TYPES—These cases are said to be common during the decline of an epidemic. It is at present quite impossible to say with what frequency they occur, because it is certain that many of them are overlooked. They are often treated as cases of "influenza", owing to the resemblance they bear to that disease. Many cases of acute fever with headache and pains in the back and limbs are regarded as "influenza" from a diagnosis by exclusion. They are not subjected to a lumbar puncture because the condition does not seem sufficiently grave. And if they recover from an illness of a few days' duration this is thought to be confirmatory of the diagnosis. In the presence of an epidemic of cerebrospinal fever, however, a very close scrutiny of these cases should be made, and if there is even doubtful neck rigidity or Kernig's sign, the cerebrospinal fluid should be examined. Even when lumbar puncture is not at first decided upon a swab from the naso-pharynx should be investigated for the meningococcus.

During an epidemic a patient who presents the symptom-complex of headache, malaise, pains in the back and limbs, slight fever, and some stiffness of the neck is probably suffering from a mild grade of meningococcus infection, and should be treated as such, by a lumbar puncture and the administration of sulphonamide. Subsequent measures will be determined by (a) the course of the disease, (b) the

result of the examination of the cerebrospinal fluid; and (c) the result of the examination of the naso-pharyngeal swab. The value of these cautionary measures is sometimes made apparent by the patient becoming rather suddenly worse after a few days, when it may be quite obvious that the nature of the disease is what was originally suspected.

5 **CHRONIC SEPTICÆMIA WITHOUT MENINGEAL SYMPTOMS**—Attention has been drawn to this group of cases in which there is the association of a general blood infection, with bouts of pyrexia, often arthralgia or arthritis and various lesions in the skin—petechiæ, maculo-papular eruptions or patches resembling the lesions of erythema nodosum.

6 **POST BASIC MENINGITIS OF INFANTS (CERVICAL OPISTHOTONOS OF INFANTS)**—These cases were first described by Gee and Barlow (1878). It was formerly met with in children between the ages of 6 months and 2½ years, but is now virtually never seen. It is a chronic hydrocephalic form of the disease which occurs only when the diagnosis has not been made in the acute stage and when the child has been deprived of specific treatment.

Complications—It should be stressed that complications are rare now that chemotherapy has provided such an effective means of treating cerebrospinal fever. The following descriptions are applicable largely to the days before sulphonamides were used.

1 **Hydrocephalus** may arise soon after the onset of the disease, or it may develop, and often rather suddenly, during its course, or it may be the final anatomical expression of the infective process, the counterpart of the symptom complex seen in the chronic state of the disease. Certain symptoms are specially suggestive of the condition—pallor, cyanosis, increased frequency of the pulse with diminution in its tension and volume, shallow respirations and stupor or coma supervening rather suddenly upon a previous state of consciousness.

If hydrocephalus arise at a later period of the disease than the end of the first week it may show itself with surprising suddenness, and sometimes in patients who seem to have been improving satisfactorily. In addition, to the symptoms just enumerated, there is a recrudescence of the headache, vomiting and fever, which may have to a large extent subsided. More often it appears gradually and concomitantly with the progressive cachexia of the chronic type of infection. A valuable sign of its presence in children and adults is the presence of a resonant note to percussion over the anterior horn of the lateral ventricle (Macewen). This sign is best obtained by placing the head in an upright position and inclining it to one side. The sign is not present in infants in whom the fontanelles are still open.

Hydrocephalus of the chronic stage of the disease is seen very constantly in infants suffering from the post basic type of infection. Emaciation is a constant feature. The child lies for hours without stirring. There may be reiterated automatic acts, such as the biting of nails or the loosening and pulling out of teeth. The patients are rarely comatose. Vomiting and convulsions may occur.

2 **Psychic disturbances**—These are not very common, if the delirium and stupor are excluded. But the delirium may develop into mania, urged thereto by the violence of the headache. During convalescence it is not very uncommon to observe temperamental changes, such as puerility or emotionalism, which rarely persist for very long. Secondary dementia is, however, not unknown.

3 **Motor defects**—Cranial nerve palsies are very uncommon. There are three groups of paralytic complications, but none of them is common.

(a) **Hemiplegia** and, less often, **monoplegia** of cortical type. This usually appears at the height of the disease, and is generally of temporary duration.

(b) **Flaccid paralysis** localised to one extremity or to a part of one extremity. The tendon jerks are lost. Muscular atrophy may ensue, and R.D. may develop. The prognosis for the limb is by no means bad, and complete, or almost complete recovery is probable.

(c) *Spastic ataxia*.—It is not uncommon to find convalescent patients very unsteady on their legs when they first begin to walk. Little children often refuse to walk at all for a time, even if they had learnt to do so before the illness began. Older children sprawl about the floor. Adults tend to topple over in an indiscriminate manner. In the majority of these cases there are no signs of organic disease, and the return to a normal gait is usually only a matter of time. In a few of the cases, however, the ataxia is accompanied by exaggerated knee-jerks, true ankle-clonus and extensor plantar response: a state of spasticity. The sphincters are intact, and there is no anæsthesia or analgesia. According to Sophian, who drew attention to these cases, the pupils often remain dilated, with a sluggish light reflex. Recovery, though slow, is the rule.

4. *Special senses*.—Complications involving the eye are very variable, and yet, in relation to the essentially nervous character of the main lesions of the disease, they are not very common. Fortunately, with the single exception of that form of blindness so often seen in the recovered cases of the post-basic type of the disease, very few of the eye complications are permanent. Inflammatory lesions include conjunctivitis, keratitis, iridocyclitis and (rarely) cellulitis of the orbit. Nervous lesions include extrinsic ocular defects which are not uncommon, but are generally transitory (i.e. spasmodic). Amaurosis is relatively common in the post-basic infection of infants; it is fortunately unusual in the more acute infection of children and adults. It is in most cases unaccompanied by any changes in the optic disc, and is therefore to be attributed to cortical changes associated with hydrocephalus. In some cases, however, a state of secondary optic atrophy is present. Optic neuritis is not a common complication; but papillitis, or a lesser degree of change even than this, is said by French authors to be extremely common.

The chief complication affecting the ear is meningitic deafness. This is a common and very serious complication, serious because when it occurs it is apt to be permanent. The auditory defect generally begins early in the course of the disease, and usually before the end of the first week. It is usually bilateral, which adds to the seriousness of the trouble in the event of its becoming permanent. Deafness is still an important complication, because its early onset often precedes administration of sulphonamides. Banks records some degree of permanent deafness in 4.67 per cent. of cases; in half of these it was bilateral and complete.

5. *Arthropathies*.—A certain degree of painful stiffness, and even swelling of the joints, is not at all uncommon as a transitory symptom in cerebrospinal fever. Occasionally, however, one joint shows evidence of much more intense infection, becoming red, swollen and very painful with the slightest movement. It may suppurate, and secondary infection may occur.

6. *Other complications* are the broncho-pneumonia already referred to in little children; occasionally pneumonia in adults; and enteritis.

LUMBAR PUNCTURE.—In any suspected case of meningitis a lumbar puncture is as clearly indicated as is puncture of the chest in a suspected case of pleuritic effusion, or a blood-count in a suspected case of leukaemia.

THE CEREBROSPINAL FLUID IN MENINGOCOCCUS MENINGITIS.—1. *Pressure and the amount*.—The pressure in the early stages is generally more than 200 mm. of cerebrospinal fluid as measured by a manometer fitted to the lumbar puncture needle. The amount of fluid which flows away before the normal pressure is re-established depends upon the pressure and the consistency of the fluid; it averages about 30 ml.

2. *Naked-eye appearance*.—Various grades of turbidity are met with, from very slight opalescence to a highly purulent exudate. The degree of turbidity varies with the stage of the disease at which the lumbar puncture is undertaken. In the invasion stage the fluid may be clear; in the acute meningitic stage the fluid shows marked turbidity; later, again, as the inflammatory phase passes, the fluid becomes clearer. The presence of blood probably always means that a vessel has been punctured by

the needle. Some flakes of fibrin appear.

3. *Chemistry*.—Ten to 200 to 300 mg. per ml. The globulin is diminished and often absent. The chloride content also is lowered as in other forms of meningitis: it is seldom less than 700 mg. per cent., whereas in tuberculous meningitis a reading below 680 is the rule.

4. *Cytology*.—In the early or invasion stage of the disease there is a quantitative increase in the lymphocytic content, a fact which often escapes observation if the lumbar puncture be delayed. With the arrival of the acute meningitic inflammation the chief cell present is the polymorphonuclear, usually in large numbers. At the stage, therefore, at which most lumbar punctures are undertaken, the cell content is chiefly polymorphous (70 per cent. to 80 per cent.). Later, when the stage of chronic hydrocephalus ensues, the lymphocyte again becomes the dominant cell, and in much greater numbers than in healthy fluid. Most observers, however, describe cases of undoubted meningococcus meningitis in which the cell content is chiefly lymphocytic throughout. In the post-basis type of the disease the cells are most often lymphocytes for the greater part, and the same may be said of cases which are in a chronic stage whilst under investigation, whether the chief seat of the effusion be at the root of the bulb or elsewhere.

5. *Bacteriology*.—Films made direct from the cerebrospinal fluid, or, better still, from the centrifuged deposit, show intra- and extracellular meningococci in the great majority of cases at some time or other in their course. If a careful search be made and no cocci are discovered, it must not be assumed that none are present until the device of incubating the fluid as a whole before it has been allowed to cool is undertaken, and until cultures made upon suitable media are found to be sterile. The number of cocci seen, and their disposition with regard to the cells of the exudate, are matters of great variability. These things depend in the main upon (a) the stage of the disease, (b) the intensity of the infection and (c) the influence of treatment.

Diagnosis.—The chief difficulty lies in not suspecting the presence of the disease. It is, of course, much more easy to bear in mind the possibility of cerebrospinal fever during the presence of an epidemic than at other times. It is the sporadic case, although it is usually typical, which goes undiagnosed, at least during the early part of its course.

The reason why it may not be possible to decide on clinical grounds whether meningitis is present or not is because several infective processes, other than that due to the meningococcus, are apt to produce symptoms highly suggestive of meningeal irritation. This state of meningeal irritation, when due to toxæmia and not due to actual meningitis, has been termed *meningism* or *meningismus*. The question whether such a state is entirely toxic, or whether it is due to definite though slight changes in the meningeal tissues which just stop short of an inflammatory exudate, is problematical.

quent days also, at a time when the invasion period of the infection may be said to be passed, it is evidence of meningitis

(3) *Pulse and respirations*—Irregularities in rhythm are in favour of meningitis, and so is a relatively low pulse-rate in comparison with the height of the temperature, provided typhoid fever can be eliminated

(4) *Papilloedema*, though its presence is much in favour of meningitis as against toxæmia, is not of much value in this connection, because it is usually absent at the early stage of the disease when the diagnostic problem requires urgent solution

(5) *Cervical rigidity and tautness of the hamstrings*, though suggestive of meningitis, are often present in meningism

These five points are worthy of the most critical investigation. All other clinical features that may be present are equivocal—they may be produced by a toxic state of the brain or meninges. This statement refers to the state of the pupils, whether contracted or dilated, the presence of *tâches cerebrales*, the absence of the superficial or of the deep reflexes, the "peevisish" state of the patient with a resistant attitude, marked insomnia or persistent stupor

(a) *Influenza*—This probably gives most difficulty in actual practice. It should be noted that cerebrospinal fever is very often mistaken for influenza, whereas influenza is rarely mistaken for cerebrospinal fever. The reason for this lies in the fact that the diagnosis of influenza is too often by exclusion. Fever prolonged past the fifth day, in the absence of an inflammatory focus (bronchitis, pneumonia, pleurisy, sinusitis, etc.), is unlikely to be due to influenza, and should therefore lead to a critical revision of the diagnosis. A leucocyte count is often helpful

(b) *Typhoid fever*—The onset of the illness is nearly always a gradual one, and the evolution of the toxic symptoms is much more deliberate than in cerebrospinal fever. This is perhaps the most significant differential point clinically. The leucocyte count is very helpful, and may prove of great diagnostic assistance before Vidal's test is available: the count is low in typhoid (2000 to 7000), but it is high in cerebrospinal fever (15,000 to 40,000). The rose spots of typhoid do not appear until the eighth or tenth day, whereas the rash of cerebrospinal fever which might be confused with these usually appears much earlier. If the spleen is palpable in cerebrospinal fever this is the case early, whilst the disease is at its "septicæmic" stage, in typhoid the spleen can rarely be felt before the end of the first week. The dissociation of headache and delirium in toxæmia already referred to is strikingly seen in typhoid fever. Moreover, the disappearance of the headache altogether, which occurs so frequently in typhoid fever after the tenth day, is another point of distinction, although its severity may diminish, it is rarely absent so early in the course of untreated cerebrospinal fever. As soon as a positive Vidal test is obtained (usually about the seventh to tenth day) this finding, together with a leucopenia, may be relied upon as decisive in favour of typhoid. A positive blood culture may often be obtained before the agglutination test is available

(c) *Pneumonia*—Acute pneumococcus infection is the most common cause of a toxæmic state leading to meningism, the patient is usually a child, but not always, the lung consolidation is often apical and therefore the more easily overlooked. The symptoms of meningeal irritation may precede the signs of pulmonary disease, in which case the diagnosis can only be settled by lumbar puncture, or they may concur with such signs, in which case some care must be exercised lest the case be one of cerebrospinal fever ushered in by pneumonia. Here the leucocyte count is of no help, for there is a high leucocytosis in pneumonia as in cerebrospinal fever. A blood culture may reveal pneumococci, or a chest radiogram may yield evidence of the nature of the infection, but if the diagnosis is considered in serious doubt, it will probably be deemed wise to perform lumbar puncture

(d) *Malignant small pox*, on the authority of Milligan simulates cerebrospinal fever very closely, on account of the sudden onset, headache, vomiting and pain in

the back. But as the eruption occurs on the third or fourth day the diagnosis is not left long in doubt.

(e) *Rheumatic fever*—If cerebrospinal fever begins with arthritis and profuse acid sweats, if the patient is an adolescent, and if the pains are specially referred to the joints, the diagnosis of rheumatic fever is at first pardonable. The addition of an erythema makes the simulation all the closer. The failure of salicylates to relieve the pain, or to reduce the fever, should at once arouse suspicion. The important distinction between early rigidity of the neck in meningitis and rheumatic stiffness—that the former tends to increase with examination, and the latter tends to decrease—should be remembered in this connection.

2 DIFFERENTIAL DIAGNOSIS OF CEREBROSPINAL FEVER FROM CERTAIN DISEASES OF THE CENTRAL NERVOUS SYSTEM—The most important of these diseases sometimes introducing a difficulty is

Poliomyelitis (infantile paralysis)—This disease, like cerebrospinal fever, exists in epidemic and in sporadic forms. Of recent years there have been several epidemics in England. Sporadic cases are common. If the type of the disease is the usual one, little or no difficulty is introduced in diagnosis from cerebrospinal fever, because the invasion or febrile stage is short and the degree of illness it involves is not great and there may be retention of urine, it is quickly followed by the paralytic stage, and the real nature of the malady becomes manifest. In the meningitic form of the disease a real difficulty may present itself. There may be added to the headache and vomiting pain and stiffness in the neck and spine, and even some degree of opisthotonos. Careful study of the cerebrospinal fluid usually serves to differentiate the two diseases.

3 DIFFERENTIAL DIAGNOSIS OF MENINGOCOCCAL FROM OTHER FORMS OF MENINGITIS—(1) *Pneumococcal meningitis* is rarely primary, almost always it complicates consolidation of the lung, or pleurisy, or otitis media, or infection of the nasal sinuses. When it occurs it is apt to be extremely acute.

(2) *Streptococcal meningitis* usually complicates some infective process about the skull, and most often this is middle ear disease or sinusitis. In the majority of cases some surgical procedure has been attempted for the relief of the primary condition.

(3) *Hæmophilus meningitis* is uncommon and diagnosis depends upon the isolation of *H. influenzae* from the cerebrospinal fluid.

(4) *Typhoid meningitis*—A true infection of the meninges may occur in typhoid fever, but it must not be inferred that a patient necessarily has typhoid meningitis because the bacillus is grown from the lumbar puncture fluid. This may occur without clinical evidence of meningitis and without histological and chemical changes in the cerebrospinal fluid characteristic of meningeal inflammation.

(5) *Tuberculous meningitis*—After cerebrospinal fever this is the next most common form of acute meningitis and therefore deserves fuller mention. The most helpful points in a differential diagnosis from meningococcus meningitis are the following. Tuberculous meningitis is rarely so sudden in its onset, the meningitic symptoms being preceded by a longer period of malaise, which begins less abruptly than the invasion symptoms of cerebrospinal fever. The temperature is seldom high, except as an ante mortem event, the usual range being 99° to 101° F. Retraction of the head is transient and ill marked, or is absent. Photophobia is more common than it is in cerebrospinal fever. In adults aphasia is often a common and an early symptom. True (paralytic) squint is common. The 'peevish' condition in children is much more marked during the first week. In both children and adults the depth of the stupor after about the tenth day is much greater. The discovery of tubercles in the choroid is pathognomonic, but these lesions rarely appear before the third week of the disease, and are therefore not of much service for diagnosis. Some authors lay stress upon the presence of signs of tuberculous disease elsewhere in the body as assisting in the diagnosis, but this is, of course, not true. Except in the case of adults and by no means always then, there are rarely any such signs. The leucocyte count affords no

differential help as from cerebrospinal fever, a leucocytosis of considerable size (15,000 to 30,000) being present in tuberculous meningitis. The abdominal reflexes are usually retained, whereas in meningococcal meningitis they are prone to be lost early.

However high a degree of probability that a patient is suffering from meningitis may result from a general examination, confirmation of this view rests entirely upon the results of lumbar puncture. For three reasons it should not be deferred: it establishes the diagnosis that meningitis is present, it decides the nature of the infection, it is a valuable aid to treatment in the event of a positive result.

Prognosis—The mortality in cerebrospinal fever is undoubtedly higher in the epidemic than in the sporadic cases, if the post basic meningitis of infants, in which the mortality is very high, be excluded. There are, however, no good figures upon which to base an estimate of mortality in the sporadic cases. In epidemics the mortality prior to the introduction of serum treatment was about 70 to 80 per cent. After its introduction the mortality fell to half this figure. With sulphonamide treatment the figure is probably below 10 per cent. In Banks's series of 706 consecutive cases, seen between 1939 and 1947, the mortality rate was 7.36 per cent.

The influence of age is noteworthy. The disease has a high fatality in infants, 23.6 per cent of 76 cases below the age of 1 year (Banks). The mortality is lowest between the ages of 5 and 10 years, it becomes high again in the elderly.

A fulminating form of onset is invariably bad, and the mortality in these cases is very high, if indeed it is not 100 per cent. In the cases with less vicious invasion symptoms one or more of the following symptoms betokens a grave issue: early loss of consciousness, wild delirium, persistent insomnia, extensive hæmorrhagic eruption, cyanosis. Later in the course of the disease the worst sign is the appearance of hydrocephalus.

The degree of fever, the intensity of the headache, the amount of rigidity, the presence of marked emaciation, frequency and irregularity of the pulse, rhythmical respirations, the presence of herpes—none of these things yields any information of value in predicting the issue of the disease. In few other diseases, if in any, is it possible for the patient to be so ill and yet to recover completely, as in cerebrospinal fever.

The most important fact bearing upon prognosis is the stage in the disease at which treatment is begun.

Treatment—1 **PROPHYLACTIC**—The principles governing prophylaxis are those applicable to infectious diseases in general. Although it would appear that the healthy carrier is more responsible for the spread of the disease than the patient himself, it is none the less important to isolate every case of the disease and to exercise all precautions against further contact with healthy persons. Whenever possible the patient should be transferred to a hospital, and preferably to an institution where the staff is accustomed to deal with infectious diseases.

All contacts who are found to be carriers should be placed under quarantine, and should be kept there until the naso-pharynx is free from meningococci. This is soon effected by the use of a penicillin sulphathiazole snuff. If a case occurs in a closed community *e.g.* a school, the inmates should be given sulphadimidine 3 g daily by mouth for 3 days.

2 **CURATIVE**—(1) **Drug treatment**—The introduction of the sulphonamides has revolutionised the treatment of this disease. It is of vital importance that the drug should be given at the earliest possible moment after the diagnosis has been made or is strongly suspected. Sulphathiazole and sulphadimidine (Sulphamezathine) are the drugs of choice. It is important in any case of more than slight severity to secure an effective concentration of the drug in the blood as rapidly as possible, the first dose should therefore be given by the intravenous route. In adults the initial intravenous dose should be 2 g, followed by 1.5 g orally every 4 hours for 2 to 3 days thereafter 1 g 4-hourly for 2 days and finally 1 g 6-hourly for 2 days. For children up to the age of 3 years, these doses should be 0.5 g intravenously, 0.5 g orally

4-hourly for 4 to 5 days, 0.5 g 6-hourly for 2 days. Between the ages of 3 and 15 years 1 to 2 g should be given intravenously followed by 0.75 to 1 g, 0.5 to 0.75 g and 0.5 to 0.75 g for the periods and at the intervals specified for adults. Throughout the course of treatment an adequate intake of fluid is essential, and it is wise to prescribe enough alkali, in the form of sodium bicarbonate and sodium citrate, to keep the urine alkaline. In no circumstances should a sulphonamide be given by intrathecal injection, as such a solution is strongly alkaline. Penicillin by parenteral injection, 30,000 units 4-hourly or its equivalent, is indicated in all cases of the superacute and fulminating types and where septicæmic symptoms are evident. It should never be given in meningococcal infection by intrathecal injection because no advantage follows its use and it may provoke an aseptic meningitis.

Serum treatment is now obsolete, there is abundant evidence that its use in conjunction with the sulphonamides does not improve the results obtained with the drug alone.

The persistence of an ensuing temperature of 99° to 100° F. does not necessarily imply that the infection is still active.

(2) *General management*—The diet is to be adjusted to the patient's condition. The disease is an exhausting one, and as full a dietary as is consistent with the state of the digestive secretions is to be allowed. If the fever is a conspicuous feature, and the patient is drowsy or delirious, the mouth is usually dry; the diet is then necessarily restricted to fluids, which should be given in the form of diluted milk, and freshly prepared meat essences, in small quantities at frequent intervals. Water should be given freely. If the patient is in a state of stupor the act of swallowing must not be relied upon; feeding must then be by the passage of a nasal tube three or four times in the 24 hours. According to the age of the patient, from 5 to 10 oz of citrated milk and water (equal parts), or of peptonised milk, are allowed to run into the stomach from a funnel attached to the tube and held at the necessary height above the bed. If vomiting is troublesome, peptonised milk should only be used, or whey or albumin water. If this symptom is persistent, it may be advisable to put no food at all into the stomach for 24 to 48 hours, relying upon maintaining the supply of fluid by the rectal or intravenous routes.

Urinary difficulties do not usually occur unless the patient is unconscious, in which case it is important to bear in mind the possibility of retention, which may lead to "overflow incontinence". This condition indicates the use of the catheter, with the customary care in the matter of asepsis.

(3) *The treatment of certain symptoms*—Headache is usually the most distressing symptom calling for special treatment. Phenazone, caffeine and acetylsalicylic acid may all be tried in full doses, morphine may be imperative in some cases, because nothing else may be of any service. If restlessness, delirium and insomnia are troublesome, paraldehyde or one of the barbiturate drugs should be prescribed.

The pains and the stiffness are best treated by warm baths at a temperature of 102° to 104° F.

In arthritis the affected joint is best treated by fixation and the application of hot stupes. If the effusion becomes considerable, or does not quickly yield to these measures, the joint should be aspirated.

(4) *The repetition of the lumbar puncture*—A lumbar puncture of necessity precedes the diagnosis, but there is seldom need to repeat it. The cerebrospinal fluid is usually sterilised within 48 hours after adequate dosage with sulphonamides and there is no advantage in repeated "drainage".

(5) *Treatment of hydrocephalus*—If a condition of hydrocephalus has been diagnosed, it is advisable to tap the lateral ventricles. This procedure seldom allows the normal circulation of the cerebrospinal fluid to re-establish itself, but in infants hydrocephalus often resolves after some months. If chronic hydrocephalus becomes established the intervention of a neuro-surgeon will be necessary.

GONORRHOEA

Definition.—This is an infectious disease due to *Neisseria gonorrhoeae* or the *gonococcus*, sometimes known as the intracellular Gram-negative diplococcus of Neisser. As its name implies, it is a paired organism and microscopically it may be seen that the paired cocci have adjacent surfaces flattened or slightly concave with a narrow but appreciable interval between them. It is a strict parasite and depends for spread upon direct transference from host to host. It is very susceptible to environment and is rapidly killed by drying or by weak antiseptics. It seldom survives for more than a few hours outside the body except under conditions of artificial cultivation.

Modes of Infection.—Sexual intercourse is by far the most common and important mode of infection. The organism may also be transmitted to the conjunctival sacs of newly-born infants by contamination with infected genital secretions of the mother. Occasionally, accidental contamination occurs from infected material; female children are particularly susceptible to infection in this way.

Diagnosis.—This depends on finding intracellular organisms with the typical morphology and staining reactions within the cytoplasm of polymorphonuclear leucocytes. Extracellular organisms cannot be accepted as gonococci. Legal proof of gonorrhoea rests upon the demonstration of organisms having all the cultural characteristics of gonococci. There are, of course, many other causes of discharge from the urethra and from other sites which the gonococcus may infect. A positive complement fixation test for gonorrhoea in blood serum is in itself only presumptive evidence of gonococcal infection, but it is a finding which should stimulate further search for other evidence of gonorrhoea.

GONORRHOEA IN THE MALE

This presents as an acute infection of the mucous membrane of the urethra. The disease commonly remains localised to the urethra and its communicating structures, but sometimes it invades the blood-stream and affects distant structures.

Symptoms and Signs.—The incubation period is commonly 3 to 10 days. The clinical onset is variable but at first there is usually a slight tingling discomfort in the urethra, followed by a thin discharge which quickly becomes mucopurulent, and then frankly purulent. There is likely to be a variable degree of dysuria and perhaps slight frequency of micturition. The patient usually feels quite well but there may be slight constitutional disturbance. On examination the margins of the external urinary meatus are red, oedematous and pouting. There is a yellow or greenish-yellow purulent discharge. It is important to be sure that the discharge comes from within the urethra and not from under the prepuce. The urine is hazy, due to pus. If the infection has reached the posterior urethra, a development which takes place in about 10 to 14 days in the ordinary untreated case but occasionally much more quickly, the patient may complain of increasing dysuria and of some frequency of micturition. In severe cases a few drops of blood may appear at the end of micturition, but marked hæmaturia is quite rare. Such patients may show evidence of toxic absorption, such as headache, malaise, increased pulse-rate and pyrexia which is usually of low degree but may reach 103° to 104° F.

Treatment.—The antibiotics in common use are all effective in the treatment of uncomplicated gonorrhoea. Single intramuscular injections of from 300,000 to 600,000 units of suspension of procaine penicillin in oil or water are commonly given. The smaller dose is usually effective and is preferable because it is less likely to mask the symptoms and signs of a coincident syphilitic infection. The precautions recommended to prevent masking of syphilis are given on p. 220. Some prefer to

The patient should not pass urine during the 3 hours preceding the investigation. If the infection has reached the chronic stage the gonococcus may be hard to find and a series of tests may be required to demonstrate it.

Treatment of uncomplicated infection in the female is the same as that in the male.

Local Complications.—The following local complications may occur in the female :

- (1) Skenitis.
- (2) Bartholinitis.
- (3) Metritis and endometritis.
- (4) Salpingitis, oophoritis and pelvic peritonitis.
- (5) Proctitis.

Metastatic Complications.—These may occur in males or females but are far more common in males. They are as follows :

(1) *Arthritis*.—More than one joint is usually affected. The knees, ankles and joints of the feet are the commonest sites.

(2) *Rheumatism*.—Involvement of soft tissues may occur with or without arthritis. The commonest site is the plantar fascia, especially its posterior attachment to the os calcis.

(3) *Metastatic conjunctivitis*.—This is sometimes found in association with arthritis. It is bilateral and the gonococcus cannot be isolated.

(4) *Iridocyclitis*.—This may occur in association with arthritis or as a separate manifestation. It is prone to relapse after apparent cure of the disease.

(5) *Gonococcal septicæmia* with endocarditis and pericarditis is a rare complication.

For detailed consideration of the complications of gonorrhœa, local and metastatic, of gonorrhœal ophthalmia in adults and older children, of ophthalmia neonatorum and of gonococcal vulvo-vaginitis and their treatment, and of tests for cure of gonorrhœa, reference should be made to textbooks of the venereal diseases.

AMBROSE KING.

DIPHTHERIA

Definition.—A disease caused by the Klebs-Loeffler bacillus (*Corynebacterium diphtheriæ*), characterised by a membranous exudate at the site of infection and distinctive sequelæ of toxæmic origin, the chief being acute circulatory failure, paralysis and albuminuria.

Ætiology—Diphtheria is commonest in temperate climes. Human carriers are the cause of its endemic prevalence; local conditions being merely contributory. In its seasonal prevalence diphtheria resembles typhoid and scarlet fever, the maximum incidence being in the autumn and winter months. An epidemic tendency is noticeable in years of deficient rainfall. Formerly a disease of rural districts, diphtheria is now endemic in cities and shows a tendency to local epidemic outbursts. Its heaviest incidence is on children between the ages of 2 and 5 years, at which age period it is the second most fatal disease of childhood, taking first place in the second decade. New-born infants are rarely attacked. Many cases occur in adults, and rather more females than males are affected.

Catarrhal conditions of the throat predispose to the infection; convalescents from measles and scarlet fever, and in less degree those recovering from whooping-cough and influenza, are very liable to contract the disease, which in the case of recent measles or scarlet fever may assume a particularly severe form. A progressive increase in infectivity and severity is often noticed during epidemics, and of late

years outbreaks of unusual severity have been reported. The immunity afforded by diphtheria is short lived. Actual relapse is rare, but second attacks may occur.

The disease is highly contagious and infection is by direct or indirect contact. It is seldom air borne even over a short distance. The organisms reside in the secretions from the nose and throat in detached shreds of false membrane, and at times in discharges from the ears, the vulva, sore fingers, infected wounds or skin lesions.

Direct infection may result from kissing or the reception of droplets of fluid ejected by speaking, coughing or sneezing. Indirect infection may be caused by eating or drinking utensils, handkerchiefs, towels, throat spatulas, clinical thermometers, toy trumpets, slate pencils and the like. The diphtheria bacillus readily grows in milk and produces no suspicious changes, milk thus may serve as a vehicle for spread of the disease. There is no evidence that it is conveyed by drinking water. The diphtheria of birds, cats and most other animals has not proved communicable to man and is due to a different organism, but virulent diphtheria bacilli have been found in nasal discharges and open sores of horses.

Diphtheria bacilli retain their virulence for long periods if protected from sun light and from currents of air, hence the possibility of transmission by fomites. Sterilisation by boiling water or in the steam chamber is quite effectual.

Carriers—Convalescents may harbour virulent bacilli in their throats as also may others who have been in contact with the infection. Most are free from bacilli 4 or 8 weeks after the commencement of the disease, but in some the carrier state becomes chronic. The dangerous chronic carrier is usually an immune person as shown by a negative Schick reaction. The presence of bacilli in the throat secretions of carriers is apt to be intermittent. All carriers are not equally effective distributors of the disease. Intimate contact and addiction to such habits as kissing, sneezing, spitting and pencil sucking are important in this respect. The nasal carrier is believed to be an especial source of danger. Among school children 80 per cent of the carriers are between 5 and 8 years of age, and male carriers are two or three times more common than female. Throat and nose operations on carriers may be followed by clinical diphtheria. In the search for carriers, pallor, unhealthy tonsils and nasal discharge are important indications as also a history of recent sore throat. Skin carriers are the subjects of eczematous or impetiginous lesions or whitlows. The discovery of bacilli which morphologically resemble diphtheria bacilli does not necessarily prove they are virulent. Bacilli removed from the throat are rarely harmless but those recovered from the anterior nares, from discharging ears and from the skin often prove to be non virulent when tested on guinea pigs.

The Klebs-Loeffler bacillus is a non motile Gram positive non sporing organism which shows a great tendency to appear segmented or clubbed. The bacilli are slender rods, straight or slightly curved and of varying length and thickness. In films they often show a characteristic grouping which recalls the letters of the Chinese alphabet. Both long and short forms occur, the length varying from 2 to 6 μ . The segmented appearance of the protoplasm is relied upon for morphological identification. A rapid diagnosis may be made from smears prepared direct from the throat but it should be confirmed by examination of a film made from a young (6 to 18 hours) culture on blood serum or Loeffler's medium. Diphtheria bacilli ferment glucose with formation of acid but fail to ferment saccharose. The true bacilli have been divided into *gravis*, *intermedius* and *mitis* varieties according to their virulence. Differences in growth on a special blood tellurite medium coupled with starch fermenting power in the *gravis* type and a hæmolytic tendency in the *mitis* variety are the chief distinctive features. There is some correlation between the strain of bacillus and the form taken by the infection: the *mitis* variety seldom causes profound toxæmia, but affects the larynx more frequently than the *intermedius* or *gravis*,

these two latter may cause the disease in all grades of severity, but the mortality from *gravis* strains is higher

Pseudo-diphtheria bacilli, which, although identical in appearance with diphtheria bacilli, are non-virulent, are frequently found in the nose and ear, more rarely in the throat. Another non-virulent organism of the same group is Hofmann's. This appears in smears as a diplo-bacillus, the elements of which are short, squat and wedge shaped with apposed bases. It stains uniformly throughout, and is shorter than even the shortest varieties of the diphtheria bacillus. These distinctions apply only to young cultures. Hofmann's bacillus does not produce acid in glucose, or in saccharose media, and is thus further distinguished. The xerosis bacillus, obtained from the conjunctiva, also resembles the true diphtheria bacillus, but it produces acid both in glucose and in saccharose media.

The crucial test of the identity of the diphtheria organism is the prevention of the local or general action of an injected broth culture by the previous injection of diphtheria antitoxin into the test animal. Two guinea-pigs are customarily employed, one of which has been protected by the injection of diphtheric antitoxin. Subcutaneous injection of a culture of virulent diphtheria bacilli kills the unprotected animal in 48 hours and examination will show the characteristic suprarenal hæmorrhage.

In the throat, diphtheria bacilli are often associated with streptococci, staphylococci, or the fusiform bacilli and spirochaetes described by Vincent. Of these, streptococci are most important, as cases of septicæmia have been attributed to them. Diphtheria bacilli rarely become disseminated in the blood-stream but have been found in the lungs and the cervical glands.

Pathology.—The constitutional disturbance caused by diphtheria is toxæmic, toxins but not bacilli being absorbed from the primary lesion, probably by the lymphatics. The extent, thickness, persistence and situation of the membrane determine the degree of toxæmia produced. In the formation of membrane, epithelial necrosis first occurs and is followed by inflammatory effusion from the subjacent tissues. This gives rise to the membrane in which stratified fibrin entangles epithelial cells, blood-cells and leucocytes. Nearly the whole of the process occurs outside the basement membrane. Bacilli are found in the false membrane and necrotic material, but not in the healthy tissues beneath. Recently formed membrane is firm in texture and has a glistening or somewhat gelatinous appearance. The tonsils are the common sites of the first membrane formation, but the faucial pillars, the soft palate, the pharynx, the epiglottis and the larynx may be implicated. Extension from the larynx along the trachea and main bronchi is not uncommon, but coherent membrane is rarely found in the bronchioles. Diphtheric membrane is much more firmly adherent to the mucous membrane of the fauces than to the epiglottis, the larynx and lower air passages. Its appearance in the cavity of the mouth, on the tongue or lips is rare, and even more rare is its occurrence in the œsophagus, stomach or small intestine. The conjunctiva and occasionally the vulva, or a cutaneous abrasion or a surgical wound may become infected.

Apart from the membrane the morbid appearances in diphtheria are not distinctive. The condition, however, of the heart muscle is of peculiar interest. Glycogen is depleted and even in cases in which the myocardium appears healthy to the naked eye, special staining will show extensive infiltration of the muscle fibres with minute granules of mobilised fat. In advanced cases, patches of myocardial degeneration and perivascular aggregations of leucocytes become apparent. The valve escapes. The cavities of the heart may be dilated, the muscle flaccid and friable, and intracardiac thrombi, some obviously ante-mortem, may be found in the recesses of the auricles and ventricles, particularly on the right side.

The renal tubules may undergo extensive degeneration and the stomach may be acutely inflamed, with mucosal hæmorrhages and erosions.

Broncho pneumonia is not uncommon in extensive faucial and in laryngeal infections, it is usually due to secondary invaders. Emphysema or pulmonary collapse may occur where respiratory obstruction is severe, and massive collapse of the lung may result from paralysis of the respiratory muscles.

The essential nervous lesion is a patchy parenchymatous degeneration of the peripheral nerves. Changes are also found in the vagal nuclei and in the anterior cornual cells. The cerebrospinal fluid contains an increased quantity of protein, usually about 100 mg per 100 ml.

The lymphoid tissues of the body react, Peyer's patches being swollen and the spleen slightly enlarged. The liver, too, may be swollen from venous stasis and toxic degeneration of its cells.

There is evidence that carbohydrate metabolism is seriously deranged by diphtheria toxin hyper- and even hypo glycaemic blood curves being obtained.

Petechial hæmorrhages in the skin, serous membranes, heart wall and diaphragm are characteristic of hæmorrhagic diphtheria. Extensive effusions of blood sometimes occur.

Symptoms—The incubation period may not exceed 24 hours, more commonly it is 3 or 4 days, but a carrier may harbour virulent bacilli for a considerable time before showing signs of infection. The fauces are most often the site of the disease, next in frequency come the naso pharynx, the nasal passages, the larynx and trachea. Infection of the genital mucous membrane and of wounds is exceptional and of the intact skin rare.

Faucial diphtheria may occur in any degree of severity, from a mild catarrhal inflammation, the identity of which is only established by bacteriological examination, to a widespread infection in which membrane invades not only the whole throat but also the naso pharynx, nose, larynx and, rarely, the mouth, either simultaneously or in succession.

Invasion may be characterised by malaise, headache, anorexia and soreness of the throat. Vomiting occurs occasionally and sometimes shivering, rigor is rare. In children the onset is particularly insidious. Discovery of membrane often being the first intimation of the disease. The exudate in mild cases is limited to a patch on one or both tonsils, sometimes on the uvula or pillar of the fauces, sometimes on the soft palate. More rarely the posterior pharyngeal wall is first attacked. Special characteristics of the membrane are its elevation above the general surface, its well-defined edge, its glistening or pearl grey colour and its tendency to rapid spread. At first it is separable without bleeding, but later free oozing of blood occurs when it is forcibly detached. Multiple patches on the tonsils may, in the early stage, simulate follicular tonsillitis, but the patches tend to spread and fuse, limitation to one tonsil should always arouse suspicion of diphtheria.

Pyrexia is moderate or absent in mild infections. Enlargement of the submandibular glands is slight and early albuminuria so characteristic of grave attacks may be wanting.

Malignant diphtheria—When faucial diphtheria is severe it constitutes a very serious form of the disease with a high mortality. Toxæmia and sepsis may be combined in this grave form which is more common in children than in adults and in some epidemics than in others. It may develop very rapidly. The membrane is thick, tough and adherent, sometimes much discoloured. It plasters the œdematous fauces and may extend widely over both aspects of the soft palate and on the pharyngeal wall. When the membrane is spreading rapidly it may appear shiny and gelatinous, often being thin, transparent and filmy particularly at the growing edge. Nasal discharge points to implication of the naso pharynx and nose. Rarely extension occurs along the hard palate and into the sulci at the sides of the tongue. Secondary invasion of the epiglottis and larynx is not uncommon. The cervical glands become swollen and tender, and periadenitis may extend and involve the neck in a collar of cellulitis (*bull neck*). The subcutaneous tissues may then undergo widespread necrosis and

the skin become thinned and much discoloured. A brownish or bloody nasal discharge excoriates the nostrils and the upper lip. Nasal respiration is obstructed and deglutition difficult. The breath has a sickening odour, and the face is puffy or becomes ashen in colour. The skin is dry and the extremities cold. Slight general cutaneous œdema may make its appearance. The patient is restless and sleepless but apathetic. Bleeding is easily induced by interference with the edges of the membrane, and epistaxis may occur. Fever is not proportionate to the gravity of the disease; in the worst cases the temperature is subnormal. Albuminuria is usually profuse and the quantity of urine secreted may be very small, but uræmic symptoms are rare. A steady and progressive circulatory failure, characterised by a falling blood pressure and feebleness of the heart's sounds, is an ominous feature. The pulse may become soft, irregular or quite imperceptible. At this stage the urea content of the blood is elevated. Respiration is rapid and shallow. Vomiting often sets in before the end. Broncho-pneumonia can rarely be recognised by physical signs, but is often present. Death may occur within a week of the onset; sometimes however, under the influence of antitoxin the membrane clears and the faucial œdema subsides, but acute circulatory failure may still be imminent; death often occurring during the latter half of the second week. In those who escape, widespread paralysis is a common sequel.

Laryngeal diphtheria.—Infection of the larynx may be primary, but is usually a sequel of faucial infection. Essentially occurring in childhood, its frequency increases up to the fourth year of life, after which it progressively declines. The presence of membrane, even in the smallest amount, on the tonsils or fauces will afford a positive indication of the nature of the laryngitis. Failing this a diagnosis is made by swabbing, by preference, the pharynx or larynx; but treatment must not be delayed pending the result. Hoarseness and croupy cough are early symptoms, soon followed by paroxysms of inspiratory dyspnoea due to laryngeal spasm, with characteristic stridor and recession of the chest wall. During the paroxysms the patient is agitated, sweating and perhaps cyanosed. The cough is loud and croupy. With relaxation of the spasm, dyspnoea may cease and the child fall asleep from exhaustion. At first the paroxysms are mainly nocturnal, later they become more frequent and more prolonged, until finally obstruction is continuous and mechanical. Extraordinary recession of the sternum and lower ribs may then accompany the efforts to respire. The body assumes a leaden hue and death occurs from slow asphyxia. In rare instances the paroxysms of dyspnoea and cough culminate in the expulsion of membranous casts of the larynx, trachea or larger bronchi. The absence of toxæmic symptoms when membrane is limited to the larynx and lower air passages is very striking.

Laryngeal diphtheria may run its fatal course in a few days. In infants its duration may be less than 24 hours. In favourable cases the condition subsides under prompt treatment. Should obstruction persist after tracheotomy or intubation, the presence of membrane in the trachea or larger air passages should be suspected; when, however, the bronchioles are blocked, the character of the dyspnoea is quiet rather than violent. Laryngeal diphtheria in a mild chronic form is a rarity.

Nasal diphtheria.—A muco-purulent or blood-stained nasal discharge may be the only evidence of diphtheria in infants and fever convalescents. Infection may be naso-pharyngeal or purely nasal. The former is grave, as toxæmic symptoms may be pronounced, whilst localised nasal infection is more often benign and may be unilateral. In such cases a small patch of membrane may, perhaps, be found on the septum. Possible implication of the nasal accessory sinuses should be remembered. As already mentioned, bacilli from the nose may prove to be non-virulent. Foreign bodies in the nose have at times been associated with persistent nasal diphtheria.

Conjunctival diphtheria is usually the result of direct inoculation, but may extend from the nose. It may simulate a mild, simple conjunctivitis, or membrane may form on the inner aspect of the lids. There is, however, a grave form with extreme

inflammatory infiltration of the conjunctiva which may lead to sloughing of the cornea and destruction of the eye

Vulval vaginal and preputial diphtheria—Vulval infection may be secondary to diphtheria of the fauces infection being conveyed by the fingers or it may be primary. Sometimes it is seen in puerperal women. It is of insidious onset and the membrane looks like a slough on the inner surface of one or both labia. The inguinal glands are enlarged and confusion with noma, erysipelas, chancre or gonorrhœa is possible. Severe toxæmia may ensue. The vagina may be infected with the vulva. Preputial diphtheria may follow ritual circumcision. Infection of the puerperal uterus and of the male urethra is rare. Infection of the umbilicus may occur in the new born.

Diphtheritic infection of wounds is not common except under conditions of active warfare and here membrane formation is not invariable. The wound may merely be dry and grey and the adjacent glands swollen. Bacteriological confirmation is necessary. Paralysis may be confined to the region involved.

Cutaneous diphtheria—Slight infection of the macerated skin at the margins of the nostrils and mouth is frequent and diphtheritic whitlow is not rare, the finger possibly being infected by sucking. Sometimes the raw surfaces left by eczema, herpes or impetigo become secondarily infected and membrane may form but skin diphtheria may occur without this distinctive sign. Gangrenous varicella and extensive gangrene allied to noma have been attributed to the action of the diphtheria bacillus as also have some veldt or desert sores (see p. 1330). Here again paralysis may have a strictly local incidence. Before skin cases are accepted as genuine, rigorous bacteriological proof is essential.

Septic diphtheria—The ordinary grave case of diphtheria may be looked upon as toxæmic. The septic type of case is characterised by pulpy discoloured membrane and great inflammatory œdema at the site of infection accompanied, it may be by fetor, ulceration, cellulitis or even gangrene. The adjacent lymph glands are much swollen, periadenitis is marked and suppuration may ensue. Erythematous or measles rashes may appear on the extremities. Constitutional symptoms are severe and the prognosis grave, chiefly, it is alleged, because diphtheria antitoxin has no influence on the septic element which may be a hæmolytic streptococcus.

Hæmorrhagic diphtheria—Hæmorrhagic symptoms supervening during the acute stage indicate an infection of a severe type. Blood may ooze from the edges of the membrane and epistaxis occur. This in itself is not necessarily serious but the tendency to bleed may be more widespread, bruises appearing on the body and bleeding occurring around and along the track of the antitoxin needle. The conjunctivæ may become suffused with blood and hæmorrhage may occur from the stomach or bowel. Hæmaturia is rare. In some cases small cutaneous petechiæ are the only evidence of the hæmorrhagic tendency but they are of most sinister import.

Blood changes—A polynuclear leucocytosis is common in diphtheria and reaches its acme at the height of the disease. Sometimes the red cells are in excess of normal and the specific gravity of the blood increased, indicating a reduction in plasma volume with hæmoconcentration. Leucocytosis may be absent in very mild and also in very grave infections. The presence of myelocytes is also characteristic and the appearance in large numbers indicates a severe toxæmia and a bad prognosis.

Complications—The chief are circulatory failure, paralysis, albuminuria and pulmonary inflammations. Relapse sometimes occurs.

Acute circulatory failure is a justly dreaded occurrence. Apart from asphyxia and from respiratory paralysis it is responsible for all the deaths. In diphtheria, excluding the mildest cases and those in which respiratory obstruction exerts its modifying influence, there is from the first a progressive fall of blood pressure, the systolic readings being affected earlier than the diastolic. Recovery is very rare when the systolic reading falls below 65 mm. The fall in pressure is said to be accompanied by a fall in volume and increased concentration of the blood. Vascular

relaxation is believed to account for the early fall in pressure, the effect of myocardial weakness appearing later. The condition culminates in attacks of acute circulatory failure. Where systematic pressure readings have not been taken, vomiting and minor irregularities or intermissions of the heart's action often afford the first warning. True respiratory or sinus arrhythmia, which is so common in childhood and often is exaggerated in diphtheria, should not be confounded with the condition now under consideration. Tachycardia and bradycardia are both disquieting signs. The heart sounds become modified, the first becoming short and soft and the second somewhat accentuated. Reduplication and gallop rhythm may occur. Vomiting without obvious cause is always a danger signal. The characteristics of the acute attack are great irregularity and feebleness of the pulse, præcordial or epigastric pain, restlessness, rapid shallow respiration, slight cyanosis and a sub-normal temperature. The mind remains clear. Dilatation of the heart and increase in the size of the liver may be evident. Actual dropsy is rare, but sometimes slight œdema of the face, chest and feet appears. Albuminuria may supervene or, if already present, be much increased, partial suppression of urine occurs. Death often results with great suddenness, and should the first attack be survived, which is unlikely, a second or even a third may prove fatal. Rarely recovery ensues.

Death from circulatory failure is an early sequel of severe faucial infections occurring at the end of the first or in the course of the second week. Cardiac failure occurring at a later stage of the disease is often associated with severe paralytic phenomena, and in some cases, at all events, is believed to be of nervous rather than myogenic origin. The absence of residual valvular or myocardial lesions after diphtheria is remarkable. Electrocardiographic evidence of myocardial disease is frequently present. This may consist of changes indicating diffuse damage to the myocardium, low voltage curves, flattened T-waves and depression of ST segments, or signs of injury to conducting tissues, such as all grades of auriculo-ventricular block, bundle branch or intraventricular block. Auricular flutter and fibrillation may occur, but are uncommon. Paroxysmal ventricular tachycardia may be a closing event. It is rare for electrocardiographic abnormalities to appear before the sixth day, or, for the first time, after the twenty-first day of the disease.

Diphtheritic paralysis occurs in from 15 to 20 per cent of cases. It is more often localised than general, and rarely complete in degree. Palatine and ciliary, but not pupillary, paralysis are characteristic. Children suffer more frequently and more severely than adults. As a general rule, the extent and severity of the palsy are proportional to the amount of membrane which was present, but exceptionally, paralysis of diphtheritic type occurs in the absence of recognised infection. The usual time of onset is the end of the third or beginning of the fourth week of the disease, but in grave infections it may even set in before the fauces are clear of membrane. Widespread paralysis, including a dangerous bulbar variety, rarely declares itself before the end of the fourth week, and paralysis of the ataxic type, which is rare, often does not appear until the second or even third month. For a detailed description, see p 1590.

The limited form of diphtheritic paralysis is transitory, its duration being measured by days or weeks, but the more widespread paralysis may last for months or the best part of a year before recovery is complete.

Hemiplegia sometimes occurs in diphtheria and is due to occlusion of the middle cerebral artery, usually by an embolus. In most cases this paralysis is more or less permanent. Much more rarely an embolus from the heart lodges in a main artery of a limb, producing gangrene.

Albuminuria is of common occurrence, but in mild or doubtful cases its absence is not sufficient to negative the diagnosis. It is most likely to be found about the tenth day, but appears earlier and in greater quantity in grave cases. In those who recover, it is transitory and no evident damage to the kidneys results. At times

casts and a little blood may be found in the urine, particularly in toxic or asphyxial cases. Acute circulatory failure greatly increases the albuminuria and may lead to suppression of urine. Acetone often appears in the urine during severe attacks of diphtheria.

Pulmonary complications—Bronchitis and broncho pneumonia may accompany severe faucial diphtheria, but are more common when the larynx is implicated. The cause is often a secondary infection. Febrile disturbance, increasing dyspnoea, cough and lividity are the signs which should suggest implication of the lung. Auscultatory signs are often equivocal, owing to laryngeal obstruction or the presence of a tracheotomy tube. Massive collapse of the lungs, which may occur in paralytic patients, is often mistaken for acute circulatory failure, pneumonic consolidation or pleural effusion. Some degree of acute emphysema is usually present when the larynx is obstructed, and surgical emphysema of the mediastinal and subcutaneous tissues may follow a difficult tracheotomy and simulate pericardial friction. As sequels of diphtheria, lobar pneumonia, pleural effusion and empyema are rare.

Otitis media is exceptional and seldom serious. In this respect it stands in sharp contrast to the otitis of scarlet fever and of measles. Diphtheria bacilli recovered from the ear discharge are often non virulent, perhaps in 50 per cent. of the cases. Diphtheritic membrane is sometimes formed in the auditory meatus.

Relapse of diphtheria is rare. It occurs in little over 1 per cent. of the cases and usually is mild, the membrane being limited to the tonsils and rarely spreading to

and pillars of the fauces The tonsillar glands are swollen, well defined and indolent, and there is little or no fever The rapidity with which ulceration and perforation of the palate occur in some cases is striking The diagnosis is made from the history, the presence of other signs of syphilis, failure to find diphtheria bacilli, a positive Wassermann reaction and prompt response to vigorous anti syphilitic treatment

Other conditions which simulate faucial diphtheria are erysipelatous inflammation, herpes of the soft palate, lesions due to steam, boiling fluids, crustics and the trauma of tonsillectomy

Laryngeal diphtheria—Croupy cough, hoarseness and stridor in a child will always suggest diphtheritic infection Examination may show membrane on the fauces By forcible depression of the base of the tongue with a spatula, the epiglottis may often be seen and membrane possibly recognised on its edge or surface Rarely fragments of membrane are ejected on coughing or there may be a history of contact with the disease All doubtful cases should be treated freely with antitoxin, pending confirmation by examination of a swab taken from the pharynx as near the glottic aperture as possible

Other forms of laryngitis have to be differentiated They are (1) the laryngitis of early measles, distinguished by history, catarrhal symptoms and Koplik's spots (2) Simple catarrhal laryngitis, in this bacteriological examination is most essential The voice may be hoarse, and the cough croupy, nocturnal spasms of dyspnoea may occur Enlarged tonsils and adenoids are often present, and sometimes the history of previous attacks is obtained (3) The glottic spasm of laryngismus stridulus is also definitely paroxysmal but although the child crows the voice is not hoarse nor is the stridor persistent Rickets tetany and convulsions are the accompaniments in many cases

Retro pharyngeal abscess when low down, produces considerable laryngeal obstruction Digital examination of the back of the pharynx reveals its presence, sometimes the bulging may be seen on inspecting the fauces

Rare causes of laryngeal obstruction are congenital laryngeal stridor, congenital syphilis, oedema of the glottis in renal disease, or resulting from inhalation of steam or other irritants, foreign bodies in the larynx and papillomatous growths These forms of obstruction are differentiated from diphtheria by the history, by careful inspection of the fauces, followed by digital examination, by general examination of the patient and by the negative results of bacteriological examination In adults the laryngoscope will give useful information Direct laryngoscopy is also of great value

Prognosis—The important indications yielded by determination of the extent and position of the membrane have already been mentioned the more extensive and more persistent this is, the greater is the risk of severe toxæmia Cases where the membrane is limited to one, or to parts of both tonsils are likely to be mild, when both tonsils are completely covered the attack is more grave, but recovery is still probable, when the fauces and naso pharynx are extensively involved, the outlook is very serious The mortality in malignant diphtheria may, despite antitoxin, even reach 60 per cent The great mortality of laryngeal diphtheria is due to asphyxia and broncho pneumonia, absorption of toxin from this region being small Diphtheria limited to the nose and not involving the naso pharynx has a low mortality

Enlargement of the cervical glands is more or less proportional to the extent and virulence of the lesion in the fauces and naso pharynx, and has the same prognostic importance The efficiency of antitoxin treatment and the day of its first administration have a most important influence The mortality is almost negligible when antitoxin is administered on the first day of the disease, but it increases progressively to 18 or 20 per cent. if administration is delayed to the fifth or subsequent days

Age also has a great effect, the disease being very fatal to children in the first year of life, and much more serious in children under 5 than in those over that age

Malignant and septic attacks with much pallor, copious nasal discharge, considerable glandular enlargement and profuse albuminuria have a very bad prognosis

Hæmorrhagic symptoms, other than slight bleeding from the edge of the membrane and possibly epistaxis, are grave, particularly so, minute cutaneous petechiæ. Cases such as these hardly ever survive. Repeated vomiting after the initial stage, and signs of acute circulatory failure are most ominous. The chief danger of paralysis, when this ensues early, is its association with acute circulatory failure, but paralysis of the bulbar type is in itself very fatal. Failure of the muscles of respiration and deglutition with liability to broncho pneumonia and pulmonary collapse constitute the chief dangers of generalised paralysis. If the patient survives, paralysis terminates in complete recovery, but hemiplegia, which is of vascular origin, may be permanent.

Treatment—**PROPHYLACTIC**—Convalescents should be isolated for not less than 4 weeks from the commencement of the disease, or until three negative bacteriological examinations at intervals of a week have been obtained. The presence of inflammatory conditions or discharges from the throat, nose, eyes or ears is an indication for further detention. Skin eruptions and whitlows should not be overlooked.

The period of quarantine advised is 12 days. This is now generally replaced by supervision with bacteriological examinations. Children from an infected house should not be allowed to attend school until proved free from infection. Contacts in the home or school often become carriers, and should also be bacteriologically examined. Clothing and utensils which have been in contact with the sick should, of course, be disinfected.

When diphtheria breaks out in ward or institution the procedure is as detailed on p. 77. Opinion with regard to the desirability of prophylactic injections of anti-toxin is not unanimous. The symptoms of diphtheria may be prevented in contacts by the injection of 500 units of antitoxin, but this method fails if the subject is already incubating the disease, and only affords protection to others for some 3 or 4 weeks. It should be realised that antitoxin does not prevent infection, but only the toxic results of infection. It militates against active immunisation and may produce a condition of hypersensitiveness to the serum, which may have to be used subsequently.

For these reasons, the best authorities are against prophylactic injections of antitoxin in contacts and in favour of repeated examinations for signs of development of the disease, when antitoxin can be administered at once. Meantime, immunisation of susceptible contacts (*vide infra*) can be initiated, since there appears to be no negative phase induced.

In the Schick test we have a means of determining whether an individual is susceptible to diphtheria. If a local inflammatory induration from 1 to 2 cm in diameter follows the injection of 0.2 ml of diphtheria test toxin into the skin (or 0.1 ml of the U.S.A. reagent) susceptibility to the infection is indicated. The average Schick-test antitoxin equivalent is $\frac{1}{1000}$ unit. This measure of combining power is preferable to the original standard of one-fiftieth of the minimum lethal dose (M.L.D.) of toxin for a guinea pig. At the same time, but at another spot, an intradermic injection of heated, and therefore inactive, toxin is made, to discount a "pseudo" reaction due to the foreign protein in the solution of toxin. The absence of a reaction to the active toxin generally indicates the presence of more than one two-hundredth of a unit of antitoxin per c.c. in the blood, and is a sign of immunity. The injections are usually made into the skin of the forearms. The reaction takes 24 to 36 hours to develop, and another week to subside. Four types of reaction are possible: (1) Negative, (2) Positive, (3) Negative and Pseudo and (4) Combined Positive and Pseudo. These must be discriminated with care. The best time for reading the test is 36 hours after injection, and again at the end of a week when false reactions will have faded and late positive reactions will be detected.

For immunisation, diphtheria toxin, guarded by antitoxin, was originally used. Later, toxin, converted to toxoid by incubation with formalin (*anatoxine*), replaced

this Toxoid-antitoxin floccules, precipitated by interaction of toxoid and antitoxin produce little or no reaction and are effective. For the immunisation of children, alum-precipitated toxoid (A.P.T.) is now recommended. Two doses (of 0.5 ml) are given intramuscularly, with an interval of 4 weeks between them. Some prefer an initial dose of 0.2 ml. For adults, who are more liable than children to reactions, toxoid-antitoxin floccules (T.A.F.) are preferable, three injections (1 ml, 1 ml and 1.5 ml) being administered, with intervals between them of 3 or 4 weeks. Susceptibility to reaction may be detected by intradermal injection of 0.2 ml of diluted toxoid (*Moloney test*) or of the particular antigen it is proposed to use. The development of active immunity takes about 6 weeks. This immunity is protracted, but its exact duration cannot yet be specified. Most children over 6 months are susceptible and the ideal time for immunisation is in the eighth month or soon after. At the beginning of school life a supplementary dose of 0.5 ml is recommended. When the proportion of vaccinated children in a community reaches 70 to 80 per cent a great reduction of incidence of diphtheria, and of carriers, perhaps to zero, may be expected.

When dealing with outbreaks of diphtheria in wards or institutions, swabs should be taken from the throats and noses of the inmates, and Schick tests performed. The negative reactors are then isolated. They will probably include a dangerous chronic carrier as proved by the virulence test. The positive reactors may be immunised with A.P.T. or combined active and passive immunisation undertaken, injections of 500 units of antitoxin being injected into one arm and the first dose of A.P.T. injected into the other arm at the same sitting. Virulent bacilli in the Schick positive group indicate precocious carriers who will soon sicken with the disease. Measures to prevent dissemination by dust are the same as those recommended in scarlet fever (p. 46).

Chronic carriers are a great source of difficulty. The bacilli cannot be eradicated by local application to the throat or by the administration of antitoxin or vaccines. If the tonsils are unhealthy, they should be enucleated and adenoids removed, this is often successful. In nasal carriers when streptococci coexist the insufflation of sulphonamide powder twice daily for 8 days has seemed effective. Penicillin, too, may possibly be of use. Carriers should spend as much time in the fresh air and sunlight as possible. Before condemning a carrier to isolation, the virulence of the organisms should be tested and confirmed.

CURATIVE.—The patient should be isolated and strict recumbency maintained. Diphtheria antitoxin must be injected intramuscularly without delay, the result of bacteriological examination not being awaited in any case in which the diagnosis is reasonably certain. Although antitoxin can neutralise circulating toxin, it is much less effective against toxin which has become fixed in the cells of the body. It is therefore very important that the patient should receive the first dose of serum not later than the third day of the disease, the earlier it is given the better the result, but at whatever stage the presence of membrane indicates prompt dosage. The amount required depends, not on the age, but on the duration of the disease, the extent of the membrane and the degree of toxæmia. For mild cases on the first or second day 8000 to 20,000 units are sufficient, in more severe cases the dose should be 20,000 to 100,000 units, repeated in 12 hours if the membrane still shows a disposition to extend, or laryngeal symptoms are not relieved. Cases coming under observation after the third day of illness require larger doses than those seen earlier.

In malignant, advanced and hæmorrhagic infections, the antitoxin should be given intravenously, undiluted and at blood heat. Injection should be very slow, through a fine needle. The patient is then wrapped in warm blankets, hot water bottles applied and the foot of the bed raised, since rigor and collapse may follow. 100,000 to 200,000 units may be given in this way, followed by intravenous injection of 20 g. of anhydrous dextrose in the form of a 50 per cent solution in normal saline.

Infections of the intestinal tract may occur but are rare. Such infections must originate from spores, as the bacilli do not withstand the action of gastric juice.

Bacteriological Diagnosis—In a case of suspected malignant pustule direct microscopic examination will usually show the bacilli in the fluid in the surrounding vesicles. Sometimes examination of the sections of the excised malignant pustule is necessary. Cultures on agar will show in 24 hours the characteristic wavy outlined colonies. Blood cultures in man never show the bacilli until just before death. Putrefaction rapidly destroys anthrax bacilli hence the recognition of the bacillus in putrefying tissues entails careful bacteriological examination and animal experiments.

A guinea pig may be inoculated with suspected material, and if anthrax be present will usually die within 2 days and the bacilli may be demonstrated in the spleen.

Immunity—Pasteur, noting that one attack of anthrax immunised an animal elaborated a method of artificial immunity. He attenuated cultures by growth at 42.5°C . Sheep survived when inoculated with such cultures and proved immune to a subsequent injection of a highly virulent living culture. By carrying out this process of active immunity the mortality among animals was greatly lessened. Marchoux showed that the serum of such animals conferred a certain degree of passive immunity and Selavo by using a mixture of such immune serum and progressively attenuated cultures and virulent cultures obtained very high degrees of immunity in the ass. Selavo's serum is stable and if given in quantities of 40 to 100 ml at an early enough stage in the disease is almost always successful.

Symptoms—There are three clinical forms of the disease. I **MALIGNANT PUSTULE**—The site of infection is nearly always upon an exposed part of the body—face, neck, hands or forearms. The incubation period appears to be very short, perhaps not longer than a few hours. A small red papule forms, which rapidly becomes vesicular and then incompletely pustular. By the time vesication occurs there is a surrounding zone of intensely red œdema becoming a brawny induration by the end of the second day. By this time a ring of secondary vesicles often surrounds the initial lesion which has now formed a dry and almost black scab generally raised above the surface of the affected skin. A frequent associated lesion in the case of the arm is lymphangitis spreading upwards to the axillary nodes which become enlarged and painful. There is rarely much pain at the site of the initial lesion, though there is usually a good deal of itching and tenderness. Fever is almost constant and in severe cases may be quite high. The patient is then very ill with intense toxic symptoms. Mild cases occur however and in them both the local and the general symptoms are much less marked.

The prognosis turns upon the severity of the symptoms especially of the toxæmic state. Death is sometimes very rapid—it may occur within the first week.

In some cases the initial papule and vesicle are ill marked but the attendant œdema is excessive (*malignant œdema*). The mortality in this type of the disease is a good deal higher than in the type in which the pustule is well formed.

II **PULMONARY ANTHRAX**—In this variety of the infection the bacilli are inhaled with dust from infected hair or wool. The result is the rapid development of fever generally ushered in by a rigor with very intense toxic symptoms and the signs of bronchitis. Cerebral symptoms develop with great weakness. The whole course of the disease may be very short even as brief as 24 hours.

III **INTESTINAL ANTHRAX**—This is probably the least common form of the disease. The infection is due to eating meat or drinking milk from animals suffering from splenic fever. The symptoms are those of a severe gastro-enteritis—fever, vomiting, diarrhoea and intense weakness. The spleen is enlarged. This form of the disease has been found to occur in small epidemics. The mortality is high though not so high as in II.

Treatment—(1) **PROPHYLACTIC**—This consists in the specific immunisation of animals subject to the disease, the complete destruction of dead bodies and in the

careful disinfection of all skins, hair and wool, before these are handled in any industrial occupation

(2) CURATIVE—General measures are taken towards the prevention of a general infection. The pustule is kept clean, but is neither cauterised nor incised. The treatment of choice is penicillin (see p 6), which has now superseded Scavo's anthrax anti serum. The sulphonamides have also been employed successfully, and before their introduction neoarsphenamine had a vogue.

TETANUS

Synonym—Lockjaw

Definitions—An infective disease, due to the toxins of the *Clostridium tetani*, and showing itself by tonic spasm of the masseter and other muscles with paroxysmal exacerbations.

Ætiology—The bacillus of tetanus is a slender rod 4 to 5 μ in length and from 0.3 to 0.8 μ broad. It is a spore bearing anaerobe. The vegetative forms are slightly motile, and when stained by special methods show numerous fine flagella arranged all round the bacillus. In material from infected wounds, and usually in cultures after 24 hours' incubation at 37.5° C, spores occur. These are terminal, giving rise to the characteristic drumstick appearance. As cultures grow older the numerical proportion of spore bearing forms increases, and in very old cultures only spore bearing forms or spores are found.

Distribution—In nature the tetanus bacillus is found in the soil of highly manured districts, and in the dejecta of various animals, especially the herbivora, in the intestines of which it exists without causing pathogenic effects. By comparison with the wide spread distribution of the bacillus and its spores the disease is rare. In infected wounds the bacillus occurs with other spore bearing anaerobes associated with pyogenic cocci, and saprophytic organisms of various kinds. In consequence of its association in nature and infected wounds, with other organisms, the bacillus is difficult of isolation, as a large proportion of the associated organisms grow with much greater rapidity. Use is made of the fact that the spores will resist a temperature of 80° C for an hour. Suspected material is inoculated into agar or serum agar slopes or deep tubes of glucose agar, and incubated for 48 hours. The culture is then subjected to a temperature of 80° C for three quarters of an hour, and subcultures are made on agar plates which are incubated anaerobically. By this means all non sporing bacteria, and the vegetative forms of the spore bearers, are killed, and only spore-bearing organisms remain to be dealt with.

The disease follows injury to the tissues in most cases, and even when no injury is known to have occurred, it is highly probable that some slight abrasion has been present. The term "idiopathic tetanus" has been given to those cases in which no discoverable injury is present. Those wounds, usually of the hands, in which the tissues have been badly damaged rather than cleanly cut, are specially liable to be followed by tetanus infection. Cases have occurred from the use of contaminated gelatin used in subcutaneous injections, grey wool employed as padding for splints from catgut sutures similarly infected and from wounds from blank cartridges and fireworks.

Tetanus is more common in tropical than in temperate zones. A special form of the disease, *tetanus neonatorum* is peculiar to the tropics, and results from sepsis in attending to the child's navel.

Pathology—In nature the disease is produced by the introduction of infected material through an abrasion or wound which may be so minute as to escape detection. Probably there is no such thing as idiopathic tetanus, but infection is possible through the bronchial or even intestinal mucosa.

supplemented by 20,000 units of antitoxin intramuscularly into the buttock or outer side of the thigh. In cases which do not respond the intravenous injection is repeated after 12 hours. Intraperitoneal or longitudinal sinus injections may be adopted in some circumstances.

Antitoxin treatment may be followed by certain sequels due to horse serum. These are less frequent when concentrated or protein-digest antitoxins are used. They usually occur a week or more after injection and take the form of erythematous, morbilliform or urticarial eruptions, appearing first in the vicinity of the puncture. Fever, vomiting, arthritic pains or slight joint effusions may accompany the rash. The tonsils may again become inflamed (*angina redux*) and albuminuria may occur. The rashes and other symptoms are transient but may recur. Aspirin often affords much relief, and the cutaneous irritation may be allayed by weak carbolic lotions. On rare occasions rigor, dyspnoea and collapse follow the injection immediately, and death has been known to occur. These symptoms are anaphylactic in nature and may occur if the patient has been sensitised by injection of serum a few weeks previously, or even apart from this. Asthmatics are known to be particularly liable to them. When it is necessary to administer antitoxin in such circumstances, a preliminary injection of 5 minims should be given subcutaneously and the effect watched, or an intradermic test made. If no symptoms occur within an hour the full injection may be employed, otherwise desensitisation is necessary (see p. 4).

Penicillin cannot replace antitoxin in the treatment of diphtheria. There is, however, evidence that in malignant and in septic infections with much oedema and bull neck (possibly due to hæmolytic streptococci) intramuscular penicillin in adequate dosage, even up to one million units a day, causes rapid disappearance of membrane and subsidence of toxæmia. The diphtheria bacilli may disappear within 24 hours.

Absolute recumbency is essential in the treatment of diphtheria. For the mildest case a fortnight is not too long, in the average case at least a month, and for severe infections longer. When the patient is first allowed to sit up in bed the effect on the pulse should be carefully noted. No patient should be allowed to sit up whose pulse is irregular or who has recently vomited. The detection of paralytic symptoms is also an indication for rest.

Local applications to the fauces and nose are of minor importance.

In laryngeal diphtheria prompt administration of antitoxin and the use of a steam tent will generally obviate the necessity of operative interference, but tracheotomy, intubation or laryngeal aspiration should not be postponed, if restlessness, dyspnoea and recession of the chest wall are present, or paroxysmal dyspnoea has supervened.

Intubation is suitable for the milder type of case, but constant skilled supervision is necessary, as the tube may be ejected. As a rule, tracheotomy is preferable, especially if the fauces and naso-pharynx are much involved. Tracheotomy as a sequel to intubation has a very high mortality on account of the class of case in which it becomes necessary. After tracheotomy or intubation the patient is usually placed in a steam tent and the arms secured by light splints or other means. Cough on swallowing is obviated by using thickened foods or by nasal feeding. A method of feeding with the head lying lower than the body is often successful in intubated patients. If all goes well an attempt should be made to dispense with the tracheotomy or intubation tube on the third day, sometimes even sooner. Patients must be watched constantly when the tube is first removed. In cases where the tracheotomy is dry and no secretion occurs, an alkaline spray is useful.

Circulatory failure is treated by removing all pillows, raising the foot of the bed on blocks and applying a binder to the abdomen. The most absolute rest and perfect quietude are essential. Intramuscular injections of suprarenal cortical extract and oxygen inhalation have some value.

Paralysis calls for careful nursing and feeding, with avoidance of muscular exertion, but patients with transient precocious palatine paralysis may be allowed up

after 10 days if the condition is stationary. Massage and electricity may be useful during convalescence, but should be avoided in the early stages. The administration of vitamin B₁ (aneurine hydrochloride, thiamine hydrochloride, U.S.P.) is of very doubtful utility. Extensive respiratory paralysis necessitates artificial respiration with a Drinker or Bragg-Paul apparatus. Active collapse of the lung in diphtheria may be mistaken for acute circulatory failure if its special diagnostic signs are not borne in mind.

During the acute stage of diphtheria and also when albuminuria is present, milk, glucose mixtures and fruit juices are the best food. Solids may be allowed quite early in convalescence. When swallowing provokes coughing, the milk should be thickened with isinglass or cornflour. When pharyngeal paralysis is present, the patient should be fed through a large soft œsophageal tube or by nasal catheter.

The occurrence of anaphylaxis after injection of antitoxin is treated by injection of adrenaline, and by artificial respiration, by some adrenaline is given before injection of serum, as a prophylactic.

ANTHRAX

Synonyms —Wool sorter's Disease, Splenic Fever of Animals

Definition —An acute infective disease caused by the *Bacillus anthracis*. There are three clinical forms of the disease, according as the lesion is in the skin (malignant pustule) in the lung (pulmonary anthrax) or in the intestine.

Ætiology —*B. anthracis* is a large Gram positive bacillus possessing a capsule. On artificial media it grows in long filaments which, owing to the fact that the filaments do not readily break up into individual bacilli, tend to bend upon themselves and thus cause the outlines of the colony to assume a whorled appearance that is characteristic. Spores always develop in cultures in the presence of free oxygen.

In the tissues, however, the bacilli occur in straight rods measuring from 5 to 10 μ by 1 to 1.5 μ , the longer forms generally being found in attenuated cultures, and the bacilli found in the gelatinous œdema are usually longer than those found in blood. Spores never develop within the infected animal, since free oxygen is necessary. The micro organism is non motile.

In the herbivora, especially sheep and cattle, the disease occurs epidemically and the infection assumes a septicæmic type. The spleen may be two or three times its normal size, and on section may be diffuent. An impression preparation from the cut surface shows enormous numbers of bacilli together with blood cells and mononuclear leucocytes. The liver and kidneys are in similar condition, and the lymphatic system is extensively involved.

The bacilli in the blood are invariably in the vegetative form and it is only after being voided from the body that they produce spores, these being extremely resistant to adverse influences. It is claimed that spores may remain on the ground in a state of latent activity for as long as 12 years. They are destroyed by sunlight in 24 hours, but resist the usual concentrations of chemical disinfectants, they are killed by dry heat at 160 to 180° C and moist steam above 120° C for 1 hour. It is suggested that soil infection counts for little in this country, most cases being traceable to imported foodstuffs, hides and brushes.

The carnivora are relatively immune especially the dog.

Man occupies an intermediate position and the disease is always communicated to him directly or indirectly from animals. Two principal forms occur, malignant pustule, a local infection through a cut or abrasion of the skin or a hair follicle, and wool sorter's disease, an infection starting in the trachea and bronchi from the inhalation of dust containing spores.

If the bacilli or spores, free from toxin or from pyogenic cocci, be introduced into an animal, infection may fail to occur, the protection afforded being probably accounted for by phagocytosis, for if spores enclosed in a paper sac be introduced into a susceptible animal infection occurs, as the sac protects the spores from phagocytosis. The presence of pyogenic cocci, other micro-organisms, and the fragments of bone and foreign material incidental to compound fractures and gun-shot wounds, all conduce to the conditions favourable to growth of the tetanus bacillus.

The period of incubation, following infection with tetanus bacilli, varies with different animals. In man, a period of from 2 to 14 days occurs, but it may be as long as 100 days, and, as a rule, a long incubation means a more favourable prognosis.

Tetanus toxin.—The tetanus bacillus, like the diphtheria bacillus, produces its pathogenic effects by reason of the soluble toxin it elaborates. Bacterium-free filtrates of cultures, as shown by Kitasato, when injected subcutaneously into mice, cause tetanic spasms, at first in the neighbouring muscles and later more generally, and death has resulted.

Tetanus toxin is one of the most powerful poisons known, the fatal dose of a probably impure preparation for a mouse being found by Brieger to be 0.0005 mg.

Different degrees of resistance to the toxin are shown by different animals. The horse and man are the most susceptible. On a basis of weight the horse is twelve times and the guinea-pig six times as susceptible as the mouse, while the hen is two hundred thousand times as resistant. The incubation period is shorter when toxin is intravenously injected than when introduced subcutaneously, and is shorter in smaller than in larger animals.

It was formerly believed that tetanus toxin ascended the peripheral nerves, and this view, although contested by Abel, has now been confirmed by the recent work of Payling Wright and his colleagues. There is some evidence that the toxin is altered in the cells of the nervous system to a form in which it cannot be neutralised by antitoxin.

Symptoms.—The incubation period has already been referred to. The earliest symptom is, in the great majority of cases, the so-called *trismus* or painless tonic spasm of the masseter muscles. Beginning as a slight stiffness, this increases until the jaws are firmly clenched, the patient being unable to open the mouth. The stiffness may involve the muscles of the neck at the same time as the jaws, or a little later. The facial muscles are affected next, and the facies presents the *risus sardonius* due to the tension in the frontalis and in the muscles at the angles of the mouth. The muscles of deglutition are another group early affected. There is, from these parts, a steady spread of the spasm to the trunk and then to the limbs. Rigidity tends to appear early in the rectus abdominis and in the adductors of the thighs. The tendon jerks are exaggerated and attempts to elicit them produce spasms, local or general; attempts to elicit the plantar reflex may cause extension of the knee (Gordon Holmes). The tonic spasm in the muscles of the trunk, which may develop in from 12 hours to a week after the appearance of trismus, usually shows exacerbation in paroxysms, with resulting postures termed respectively *opisthotonos*, *emprosthotonos* and *pleurothotonos*, according as the muscles of the back, abdomen or one side of the body are in a state of spasm. These paroxysms may be induced by divers irritants, and are agonisingly painful; the earlier they occur the more grave is the prognosis. Retention of urine is common.

Less common manifestations include a local contracture of muscles in the neighbourhood of the wound, which may precede trismus or more general spasm by several days; the localisation of stiffness and spasm in tetanus may be a result of immunisation. Thus, in a wound of the forehead there may be a facial palsy or an ophthalmoplegia on the same side or, with a wound of the hand or foot, painful spasm of the muscles of the limb may develop before spasm appears elsewhere. In some of these local forms general spasms may be absent throughout or, if trismus

is present, this may be transient. In "*local tetanus*" the incubation period is sometimes as long as 30 days.

The disease is often apyrexial, but in some cases the temperature rises with the development of the general symptoms, which include headache, pains in the back, anorexia, constipation, insomnia, yawning, sweating and a facies of great anxiety. Hyperpyrexia may precede death. Consciousness remains clear. The cerebrospinal fluid is unaffected.

Course.—The course of the disease is variable. Sometimes it is as short as 4 or 5 days, the patient dying of spasm of the glottis, asphyxiation, broncho-pneumonia, heart failure or exhaustion. Other cases, less fulminant, last from 7 to 14 days. A few seem to deserve the term "chronic".

Diagnosis.—A relatively trivial disease which may, however, cause some anxiety from its resemblance to the trismus of tetanus, is the fixation of the jaw seen in certain cases of *septic throat* and *septic*, especially impacted, *teeth*, with phlegmonous involvement of the floor of the mouth, periosteum, etc. Careful examination of the mouth nearly always suffices to determine the real nature of these cases, and the presence of enlarged and tender cervical glands assists the diagnosis.

Strychnine poisoning presents features resembling tetanus in that the spasms are very similar in both diseases. But between the spasms in strychnine poisoning the muscles are relaxed, a condition never seen in tetanus. Another point of distinction is the fact that trismus and cervical rigidity never exist alone in strychnine poisoning, whereas they frequently do in tetanus.

In any doubtful case of injury, in which there are damaged tissues, bacteriological investigation of the exudate and of material from the depths of the wound should at once be made.

Prognosis.—This is always grave. The mortality in a large series of cases was 45 per cent. (Vinnard). Infants and children rarely recover. The absence of fever, a more or less normal pulse-rate, a long incubation period, and a slow development of the symptoms are favourable points. If the patient reaches the tenth day of the disease, his chance of recovery is considerably increased.

Treatment.—1. **PROPHYLACTIC.**—All wounds of a suspicious character should be excised under a general anæsthetic, the raw surface thoroughly treated and antitoxin administered.

Antitoxin has for some time been administered as a routine, when wounds are infected with road sweepings or garden soil and in America often in trauma sustained during Independence Day celebrations, with a consequent fall in the death rate from tetanus.

During the War of 1914–1918 antitoxin was used on an extensive scale. During the early period, with no special arrangements for prophylaxis, the incidence was about 8 per 1000. Later, with the use of 500, and then 3000 international units (I.U.), of antitoxin, the incidence fell to 1 in 1000. Following passive immunisation induced by prophylactic antitoxin, cases which do develop tetanus tend to have a longer incubation period and the disease may remain "local". But such passive immunity does not persist for more than 3 weeks; hence to ensure protection the dose of antitoxin must be repeated at fortnightly intervals where wounds do not heal.

Tetanus toxin treated with formaldehyde or alum loses its toxicity but retains its antigenic power. The material, called "toxoid", has been proved of great service as a preventive agent. At the R.A.M. College it has been proved that two doses of 1 ml. each of toxoid, given at intervals of 6 weeks, confer immunity lasting at least 2 years. This is now the practice in the British Army before a man goes on active service. The second injection is most essential in the production of active immunity for, following it, the rise in antitoxin content of the patient's serum is far greater than that consequent upon the first.

2. **CURATIVE.**—Keep the patient as quiet as possible in a dark and noiseless room.

Feeding may be impossible by mouth, in which event nasal feeding may be attempted, and if this, too, is impossible because of spasm, recourse must be had to glucose-saline rectal drip

A complete excision of the primary site or sites of infection is wise wherever this is possible

It is profoundly important that no delay whatever should occur in the use of antitoxin. Injection may be made intravenously or intramuscularly. Provided there be no contra indication to the administration of horse serum—freedom from previous serum therapy, freedom from allergic manifestations which might necessitate rapid desensitisation (see p. 4), antitoxin may be injected undiluted into the vein, although it is wiser to dilute it with 200 to 300 ml of sterile normal saline and allow half an hour for its administration. As soon as the diagnosis is suspected, 50,000 to 60,000 units are given intravenously. Antitoxin is excreted slowly and its presence in the circulation has been demonstrated at least 10 days after a large single dose given by the intravenous route (Cole). Probably nothing is gained by infiltration of the area surrounding the infective focus with antitoxin. Subsequent daily intramuscular doses of 10,000 to 40,000 units are advisable to neutralise any possible continued production of toxin.

Debate still continues over the advisability of intrathecal injections of antitoxin. The balance of opinion is opposed to it and this view is reinforced by the frequency of severe reactions and by the evidence that tetanus toxin, once fixed in the cells of the nervous system, is no longer neutralised by antitoxin. A similar dose should be administered at least an hour before any further surgical treatment or manipulation is undertaken.

Before the onset of tetanic convulsions, a mixture of chloral gr 15 and bromide gr 20 given by mouth 2 or 4-hourly, or phenobarbitone gr 3 by mouth or intramuscularly as often as required, is indicated to lessen excitability and procure sleep. Avertin or paraldehyde administered per rectum are the best remedies by which to control severe spasms. For a man weighing 10 stones (63 kg), 6 ml of Avertin or 20 ml (5 dr) of paraldehyde shaken up in 200 ml of normal saline, should suffice to hold them in check for 4 to 6 hours, after which the dose may require to be repeated. While the patient is under the influence of Avertin trismus may be relaxed and attempts at feeding are most likely to be successful 2 or 3 hours after its administration. Chloroform vapour is also of value, but when spasms are severe it cannot be inhaled. A more or less continuous use of morphine or hyoscine is an alternative measure. Some success has been claimed for the use of muscle relaxants, in particular the short acting succinylcholine, as a means of controlling the spasms. These drugs are given continuously, anoxia and pulmonary infection being prevented by tracheotomy with assisted respiration, frequent suction through the tracheotomy tube and postural drainage.

The sulphonamides and the antibiotics have little effect on tetanus itself, but may be required to deal with the secondary pneumonia which is common in the more protracted cases.

Less success has attended the therapeutic use of tetanus antitoxin than is the case with diphtheria antitoxin. This result is largely, if not entirely, accounted for by the relative slowness in the onset of symptoms in tetanus as opposed to diphtheria. The argument for the prophylactic use of antitoxin in every case of a wound contaminated with road material or soil contaminated with animal excreta becomes correspondingly strengthened.

TUBERCULOSIS

Definition—Tuberculosis is an infection of the tissues by *Mycobacterium tuberculosis*, leading to lesions which are characterised by tubercles, microscopic or macro-

scopic, themselves undergoing changes leading to caseation, necrosis, ulceration and calcification, and having in close association with them varying degrees of fibrosis. The lesions of tuberculosis form the histological and anatomical basis of a large number of diseases which differ according to the organs affected, the extent of the lesions and the degree of resistance to infection shown by the tissues.

Ætiology—**MYCOBACTERIUM TUBERCULOSIS**—The mammalian tubercle bacillus was first identified by Koch in 1882. Within a few years, two varieties, the human and the bovine, had been distinguished, and other forms, not pathogenic to man, but capable of causing disease in birds, cold blooded animals and voles, have since been added to the list.

In the tissues and secretions the bacilli which tend to occur in small groups, are rod shaped, straight or slightly curved, with parallel sides and rounded ends. They vary in length from 1 to 4μ and in breadth from 0.3 to 0.6μ . They stain with carbol-fuchsin, retaining the dye after treatment with acid and alcohol, but are not coloured by Gram's method. In culture the bacillus grows slowly, requiring special media for its cultivation, the cultural characteristics of the various types show well defined differences. *Myco tuberculosis* is capable of survival for many months in dried sputa and secretions and is much less easily destroyed by bactericidal agents than other micro organisms.

Only the human and bovine types of tubercle bacilli are of importance in human pathology, the first, in addition to causing disease in man, is responsible for cases of naturally occurring tuberculosis in monkeys, pigs and occasionally in dogs and parrots, the second occurs as a natural infection in cattle, pigs, horses, man and occasionally in dogs, cats and sheep.

The bovine bacillus is responsible particularly for infections of the cervical and abdominal lymph nodes, in England and Wales this strain causes 64.7 per cent of mesenteric and 57.5 per cent of cervical adenitis, for Scotland the figures are 78 per cent and 72 per cent. The human bacillus is found in 99 per cent of cases of pulmonary tuberculosis in England and Wales but the proportion of bovine infections is greater in Scotland, and still higher in the North of England. Osseous and genito-urinary infections are due to the bovine strain in 10 to 20 per cent of instances.

SOURCES OF INFECTION—There are two sources of infection in tuberculosis, tuberculous sputa and tuberculous milk. In 90 per cent of cases the source of the infecting bacilli is dried human sputa. Nuttall found that from 2 to 4 billion bacilli were expectorated in 24 hours by a patient whose phthisis was only moderately advanced. These bacilli are scattered freely in dust when the sputa become dried and they lie about the surface of the patient's body, or they are projected directly into the air along with particles of moisture when patients cough or sneeze or even speak loudly.

It is difficult to give an exact estimate of the incidence of tuberculosis in cattle, it is probable that about 40 per cent of all dairy cows of 5 years and over in England and some 17 per cent of all cattle were infected in 1952. The disease has been virtually eradicated from cattle in the United States, Finland, Norway and Denmark.

Modes of Entrance of the Bacillus into the Body—In approximately 99 per cent of cases of human tuberculosis the bacilli have entered the body by one of two channels—in 90 per cent this is by inhalation and aspiration into the lungs, and in 9 per cent by the intestinal route, conveyed by infected milk or swallowed material in some way contaminated with tubercle bacilli. Although 99 per cent of respiratory infections are due to the human type of bacillus, only 50 to 80 per cent of tuberculosis thought to have been acquired by the alimentary route, is caused by bovine strains. Cutaneous, subcutaneous, mucosal and placental infections account for the remaining 1 per cent—they have no interest beyond that accorded to curiosities.

There has been much debate in the past over the frequency of primary intestinal, as compared with primary respiratory, tuberculosis in children. Ghon (1912) first

showed that primary pulmonary infection was of common occurrence at this age, and later observations have confirmed his views. The relative frequency with which one or other of these routes is followed clearly depends upon the opportunities for infection which confront the child, in countries where the milk supply is "safe", the incidence of abdominal tuberculosis has declined and the proportion of respiratory primary infections has risen *pari passu*. Blacklock's (1932) figures for Glasgow children illustrated this point. In his patients the primary focus was pulmonary in 173 and intestinal in 101, 82 per cent of bacilli from the primary intestinal lesions were of bovine type compared with 27 from the primary pulmonary lesions.

SECONDARY FACTORS—The frequency, amounting to 70 to 80 per cent of all adults with which healed primary tuberculosis is found at post-mortem examination and the ubiquity of the tubercle bacillus prove the importance of secondary factors in the cause of this disease. These factors fall into two categories: those which decrease the body's resistance and those which increase the frequency or intensity of exposure to infection.

Man has a relative natural immunity to tuberculosis, but there appear to be racial, familial and individual variations. It is well known that many primitive races are unusually prone to the disease and this has been attributed by Rich to a "native deficiency in the power to develop or maintain acquired resistance". Familial and individual variations are more difficult to assess, because of the varying opportunities for infection within different families, but there is good reason to suppose that they exist.

Malnutrition is generally admitted to decrease resistance to tuberculosis and it is true to say that there is a lower incidence of the disease in countries where the standard of living is high. Nevertheless malnutrition is usually a symptom of poverty and is found in association with overcrowding, inadequate hygiene and poor working conditions, it thus becomes difficult to apportion the blame between these several causes. There is, however, some evidence that a diet deficient in protein is accompanied by a higher incidence of tuberculosis.

Arduous physical labour *per se* probably has little effect on resistance, the low rate of infection in agricultural labourers bears out this view. Early and frequent child bearing has an adverse influence, the first 3 months of pregnancy and the 2 immediately following parturition are recognised danger periods. Trauma appears capable of reactivating latent disease and local tissue damage may determine the site of a tuberculous lesion. Climate has no demonstrable constant effect on incidence or resistance.

The importance of the patient's attitude to his disease has long been recognised as having an important influence on prognosis, of recent years the view has gained ground that emotional disturbance often precedes, and may precipitate, its onset. It has been suggested that victims of this disease often have in common a defect of personality which makes them unable to deal adequately with their aggressive impulses (Wittkower).

Finally, certain other illnesses lower resistance to tuberculosis amongst acute infections: measles and whooping cough are of importance while it may be a closing event in cirrhosis of the liver, chronic leukaemia, chronic alcoholism, schizophrenia and other chronic mental disorders. The incidence of tuberculosis in diabetes mellitus although still higher than in the general community, has decreased greatly since the introduction of insulin.

The factors which influence exposure to infection are mainly environmental, and of these the most important is overcrowding. This applies not only to dwelling-houses, but to places of work and recreation. The spread of infection may be favoured in lesser degree by unclean methods of preparing and serving food, by inadequate hygiene and by various trade customs.

The drinking of raw infected milk is the common cause of tuberculosis due to the bovine bacillus.

INCIDENCE AND MORTALITY.—Heaf has estimated that in 1948 there were some 180,000 patients with pulmonary tuberculosis on the registers of the dispensaries in England and Wales, from a consideration of the results of mass radiographic surveys, he concluded that there were probably about 57,000 additional cases which had eluded diagnosis. Of recent years the morbidity rate or incidence appears to have risen largely on account of the improvement in diagnostic methods and the use of mass radiography. The mortality rate, however, has declined steadily in England since about 1830 when more than one-sixth of all deaths in London were due to pulmonary tuberculosis. In England and Wales the annual mortality from tuberculosis per 100,000 was 332 for the period 1861–70, 201 for 1891–1900, 87 for the year 1930 and 36 for 1950.

The results of infection are of great variety and of all grades of intensity. The variety depends upon the tissues affected, and the route of spread of the infection. The intensity depends upon the degree of relative virulence shown by the bacillus, and the amount of resistance shown by the patient. Tuberculosis may exist without appreciable disturbance to health, and the lesions produced may be commensurate almost with the whole length of a patient's life. On the other hand, the infection may cause an illness of the most severe character, killing the patient in a few weeks. The results of infection are described elsewhere in this book under appropriate headings, but *general infection* leading to the condition termed general tuberculosis is included in this article.

Diagnosis—**THE ISOLATION AND RECOGNITION OF THE BACILLUS**—In all doubtful cases of tuberculosis this is a point of vital importance. Clinical evidence of the existence of the disease, however complete it may seem to be, must never lack the confirmation of bacteriological proof, whenever this is possible. Seeing that the only proof of the existence of the disease is the demonstration of the bacillus in material derived from the patient, attention must first of all be directed to this investigation. It behoves the practitioner, therefore, to watch jealously for any material that may be available for bacteriological use, and to be quite certain that such material is not obtainable before falling back upon indirect clinico-pathological evidence (see below) to support the diagnosis.

In cases of suspected phthisis, every effort must be made to secure sputa, and it may be necessary to check a habit of swallowing expectorated material. The single, isolated plug of mucus, which is often expectorated in the early morning, should not escape attention. In little children, sputa, as such, are usually absent, but if vomiting occurs in association with lung disease the vomit should be searched for fragments of sputa. In suspected disease of the kidney or urinary tract, the urine must be collected for 24 hours and the deposit submitted to examination. Cases of *albuminuria* or of *haematuria*, in which there is not clear evidence of diffuse nephritis, should raise the question of tuberculous disease of the kidney. Stomach washings, withdrawn first thing in the morning, and the faeces should be scrutinised in doubtful cases of tuberculosis of the lung, peritoneum or bowel. If any *puncture fluid* is obtainable—as from the pleura, the spinal theca or a joint—this is valuable for investigation in any patient suspected of tuberculosis.

The methods of dealing with these materials are not difficult, though they require thoroughness and patience when the bacilli are present in scanty numbers. The very different significance to be attached to a positive as against a negative result must never be lost sight of, the former affords proof of the existence of a tuberculous lesion, the latter gives at most a presumptive evidence against it.

In dealing with *sputa*, the original carbol fuchsin method of Ziehl-Neelsen should first be tried. If the results, after carefully searching three or four films for half an hour, are negative, various methods of concentrating the bacilli are available, but culture of the sputa is the most satisfactory procedure.

Sediment from urine is best dealt with by the carbolic acid method, subsequent

centrifugalisation and staining of the deposit. The smegma bacillus (also acid fast), which may be present if the specimen has not been obtained by catheter, is differentiated by allowing the stained films to remain in alcohol for 10 minutes, the tubercle bacillus is not decolorised. In *pus*, the search is much facilitated by the use of "anti formin", and this is a useful adjunct in the examination of faeces also.

Puncture-fluids very frequently give negative results to ordinary microscopic examination, on account of the scantiness of the bacilli in them. However, the clot (if such occur), or the centrifugalised deposit, should always be searched thoroughly, as the demonstration of even a few bacilli of undoubted morphological characters is decisive. Cerebrospinal fluid should be incubated, without shaking, for 24 hours, and the "spider-web" clot stained for bacilli. Failing this demonstration, the fluid should be used for culture on Lowenstein's medium (growth takes 3 weeks), and for inoculation purposes, a guinea pig receiving a liberal amount (not less than 10 ml if possible).

Indirect Methods of Diagnosis—These depend upon the presence in the tissues of certain sensitising and immunising substances. They are indicated in doubtful cases of tuberculosis in which no material is available for investigation by direct methods (see above). The relative values of these methods are still under assessment, at present their values are probably in the order of their description here.

1 **THE TUBERCULIN TEST**—The test depends upon the fact that infection by the tubercle bacillus renders the tissues supersensitive to the toxins of the bacillus, if these be introduced into it artificially. This supersensitiveness is shown by the production of certain "reactions" which are recognisable and are regarded as more or less "specific" in their nature. Only three types of test are now employed in man.

(a) *The skin test (Pirquet's test)*—This is best employed quantitatively. Three or more strengths (e.g. 25, 50 and 100 per cent) of a solution of old tuberculin are rubbed lightly into the skin of the arm, which has been previously scarified. The appearance of papules and erythema at the site of vaccination constitutes a positive reaction.

are closely interwoven. Prevention is one of the major problems of public health and detailed discussion would be out of place, but the principles upon which it is founded are: first, control of infection; secondly, prevention of "clinical" disease; and thirdly, treatment, supervision and rehabilitation of those with active tuberculous infection.

The first includes the segregation of those with the disease in infectious form; the protection of such susceptible classes as infants and school children; and the supervision of groups especially exposed to infection, of which hospital staffs, sailors and workers in certain industries are examples. The provision of "safe" milk would alone eradicate infection due to the bovine type of bacillus.

The development of "clinical" disease can be greatly reduced by the detection of symptomless primary and post-primary infections and careful supervision of this stage. Mass radiography and tuberculin testing have greatly increased the efficiency of case-finding. Under this head, too, come measures which raise resistance to infection by improving general health and nutrition and methods of increasing specific resistance by vaccination against tuberculosis.

This last requires further discussion. Two strains of tubercle bacillus have been used for the preparation of "live" vaccines. The first, known as Bacille Calmette-Guérin (B.C.G.), is an attenuated bovine strain, incapable of causing progressive disease in man and originally prepared at the Pasteur Institute in Paris. B.C.G. was first employed in France to protect infants; more recently its use has been extended in an attempt to protect persons, such as nurses and medical students, who are exposed to infection and in whom a negative Mantoux reaction has provided evidence of special susceptibility. It is established that B.C.G. reduces the morbidity from the early sequelae of primary infection such as pleural effusion, meningitis and miliary tuberculosis; there is as yet less convincing evidence that the incidence of phthisis is much diminished. The second strain from which vaccines have been prepared is the murine type of bacillus isolated from voles by Wells in 1937. This vaccine has been shown to raise human resistance to tuberculosis, but it has not yet been widely used, and comparison with B.C.G. is not possible.

Treatment, supervision and rehabilitation of those with active tuberculosis includes the organisation of chest clinics and sanatoria together with the curative measures employed in them. These last are divided into non-specific and specific.

Non-specific measures consist in efforts at improving the patient's nutrition so as to increase the tissue-resistance to the infection—ample fresh air, plenty of good food, bodily and mental rest, and exercise undertaken in graduated fashion under expert supervision. Details of all these measures are given in the article dealing with pulmonary tuberculosis (p. 1031).

Specific methods of treatment of tuberculosis have come to occupy a place of great importance during the past few years and have completely changed the outlook in the miliary and meningeal forms of the disease. The chief of these is streptomycin, an antibiotic, usually given in conjunction with one of the chemotherapeutic agents, isoniazid or sodium aminosalicylate (see p. 1033).

GENERAL TUBERCULOSIS

Synonym.—Acute Miliary Tuberculosis.

Definition.—A disseminated form of tuberculosis, giving rise to a severe disease analogous to the septicemias in pyogenic infection.

There are two clinical forms of the disease, according as the symptoms are chiefly referable to the lungs (the *pulmonary form*), or are those of a general infection without focal signs. This latter form is often termed the *typhoid form*. The pulmonary form is described in the section dealing with pulmonary tuberculosis. In tuberculous meningitis, a common accompaniment of the *miliary form*, the infection is probably

bacilli can often be demonstrated in nasal mucus, in scrapings obtained from nasal ulcers using a speculum, and in the serous exudate from granulomata of the skin. The "snip method" of removing a small piece of skin with curved scissors, especially from the lobe of the ear, and making smears from its under-surface, is valuable. Gland puncture may also reveal bacilli. In pure nerve cases they can rarely be found unless portions of the nerves be examined. The differential diagnosis includes in nodular leprosy, lupus vulgaris, skin tuberculosis, syphilis and yaws, and in the anæsthetic type, syringomyelia, Morvan's disease, progressive muscular atrophy, peripheral neuritis, cervical rib, anhum, scleroderma and Raynaud's disease.

The *lepromin* test is useful for determining the degree of sensitisation of the skin to *Mycobacterium lepræ* or its products. The test consists of the intradermal injection of about 0.1 ml. of an antigen prepared from heavily infected tissue from a case of lepromatous leprosy. The site of injection is examined daily. Two reactions occur, the early and the late. The early reaction appears within 48 hours as a small erythematous slightly indurated area, which fades by the fourth day. The late reaction is the significant one. It appears after 1 week and progresses to the third or fourth week. It is characterised by the appearance of a visible and palpable nodule at the site of the injection which may undergo some central necrosis. The *lepromin* test is positive in many apparently normal adults and in patients with tuberculoid leprosy, negative in lepromatous leprosy and negative or weakly positive in atypical or intermediate forms. It is thus of some value in determining the type of infection in a given patient.

Prognosis—This is by no means good in more advanced cases, though with earlier diagnosis and modern treatment the disease may be arrested, the expectancy of life increased and cases sometimes cured. If the patient can tolerate maximal treatment and maintain a sedimentation rate below ten a good prognosis can generally be given. Nodular leprosy is particularly prone to such complications as tuberculosis, renal disease and pneumonia, and laryngeal and visceral involvement are serious.

Treatment—**PROPHYLACTIC**.—Lepers must be excluded from acting as cooks, waiters, etc., and segregation properly and humanely carried out is best for all parties.

doses The dose is gradually built up over the course of 2 or 3 months to the maximum recommended Toxic effects are likely if the dose is too large to begin with or built up too quickly Gastro intestinal symptoms including vomiting may occur, jaundice and agranulocytosis have been reported Lepa reactions and sometimes a condition resembling erythema nodosum usually accompanied by fever may also result from over-active treatment One of the most serious side effects is the development of severe anaemia Any substantial fall of haemoglobin concentration calls for immediate reduction or cessation of treatment When patients are anaemic, with a haemoglobin value below 70 per cent, they should receive treatment with ferrous sulphate and, if indicated, with liver preparations before sulphone treatment is started

Patients on sulphone treatment thus need to be carefully watched, especially in the early months of treatment Periodic examination of the red cell count and haemoglobin concentration should always be carried out

Treatment should be temporarily suspended or considerably curtailed if toxic side-effects develop After these have subsided, treatment must be re established cautiously and slowly

The effect of sulphone treatment on the clinical course of leprosy is best seen in lepromatous cases, in which the physical signs steadily regress The first effects noted include the healing of ulcers, clearing the nose and the arrest of eye complications with improved vision Next the tendency to chronic and subacute allergic reaction lessens, and nodules become flattened and absorbed Finally, the number of bacilli in sections of the skin and in smears from the nose decreases in number Bacilli may apparently disappear from lesions after long continued treatment

Sulphone treatment must be continued for months, if possible for some years Some authorities believe it should go on at intervals for life It is not yet possible to say whether cure results from sulphone therapy Many cases respond remarkably but others apparently equally successfully treated may relapse if the treatment regime is relaxed or stopped Any erythematous or raised appearances of the skin or thickened and tender nerves may indicate activity of the disease

Patients should be free from *Mycobacteria leprae* for at least 2 years before discharge, even then it is not possible to say whether the condition is really cured or merely arrested for leprosy is notoriously a disease of remissions

Desirable maximal adult dosages of some sulphones are given below Children usually take these drugs well and are dosed according to age and weight For example, Adams states that a child of 12 years should be given half the adult dose As stated above, small doses should be given at first and the maximal dosage reached only after 2 or 3 months

Dosage of sulphones is often restricted to 6 days in the week Some authorities recommend that treatment should be given for 3 weeks out of every 4 Others give treatment daily and continue for long periods without intermission

DIAMINO DIPHENYL SULPHONE (D D S)—It is generally agreed that sulphones act by virtue of the liberation of the parent substance diamino diphenyl sulphone (D D S) which is now coming into wider use

Dosage of D.D.S.—As with other sulphones, the dosage must be small to begin with Full dosage is reached in about 2 months, at which stage a maximum of 600 mg is given weekly in the form of tablets taken after meals Doses of 50 to 100 mg are given daily for 6 days each week, alternatively 300 mg may be given twice weekly

SULPHETONE—Oral doses up to a total of 18 to 21 gr weekly may be given in divided doses three daily after food Aqueous 50 per cent solution is equally effective and cheaper, given in doses of 300 mg thrice daily

DIASONE.—Muir recommends doses of 900 mg thrice daily after food for 6 days in the week, treatment being given for 3 out of every 4 weeks Doses of up to a total of 21 g per week have also been successfully given

THIOSEMICARBAZONE (THIACETAZONE)—Given orally up to a maximum dose of

not blood-borne, but disseminated through the subarachnoid space. It is described in the section on meningitis.

Syptoms.—The *general or typhoid form* resembles typhoid fever very closely. There is usually a period of vague ill-health—as there is in typhoid fever—preceding the more severe illness. When the latter develops there is headache, insomnia, a soft but frequent pulse, rapid respirations, a dry tongue, slight cyanotic flush and pyrexia, which is usually less continued in character than in typhoid fever. Not infrequently the temperature curve is that of a quotidian intermittent fever. In a few cases the rise of temperature takes place in the morning instead of in the evening, a feature not infrequently seen in other pyrexias of tuberculous origin, though not confined to these. Progressive loss of flesh takes place, and also *anæmia*, but this latter condition may only be found by blood examination, the dusky flush of the face often masking the blood state on mere clinical examination. As the illness progresses, suspicious signs of one or other of the more focal manifestations of the infection often arise: copious fine râles over the lungs, tumidity of the abdomen with palpable enlargement of the spleen and liver, or cerebral symptoms suggestive of meningitic involvement. In a suspected case the chest should be examined radiologically, since the suggestive “snow-storm” appearance may be present if general tuberculosis has existed for more than 10 days or so.

Diagnosis.—As the term “typhoid form” suggests, the disease resembling general tuberculosis most closely is typhoid fever. During the first week, or even during the first 2 weeks, diagnosis may be very difficult. In favour of typhoid fever are the persistence of headache, the presence of epistaxis, relative infrequency of the pulse-rate, diarrhoea and early tumidity of the abdomen. In favour of tuberculosis are a frequent pulse-rate, early cyanosis and intermission in the temperature curve. There is leucopenia in both diseases. A positive blood culture occurs during the first week in most typhoid cases, and agglutination with the patient's serum may reasonably be expected after the end of the first week.

Course and Prognosis.—The introduction of streptomycin has altered the prognosis in miliary tuberculosis from certain death to a recovery rate of about 60 per cent. The sooner treatment is started the more favourable the outlook; early diagnosis has thus become of great importance.

Treatment.—This is the same as for the pulmonary form of miliary tuberculosis (see p. 1033).

R. BODLEY SCOTT.

LEPROSY

Definition.—Leprosy is a chronic bacillary disease of low infectivity, peculiar to man, caused by the *Mycobacterium lepræ*, and associated with characteristic lesions involving the skin and mucous membranes (nodular type), and the nerves (anæsthetic type). Infection, however, may remain latent and clinical manifestations never be noted.

Ætiology.—The disease has a widespread geographical distribution, occurring in Egypt, Asia, Africa, West Indies and the Pacific Islands, etc. It is not hereditary, and individuals of any age, sex and race may be attacked. Children are more susceptible than adults. *Myco. lepræ* was discovered by Hansen in 1874; it is a non-motile, acid-fast bacillus occurring in large clumps in skin lepromata, septal ulcers and nasal mucus, and has never been cultivated with certainty. The mode of spread is unknown, but intimate contact with lepers is essential; a history of attendance on lepers, of living in the same house, sleeping in the same bed, or sexual connection is frequently obtained. Only 3 per cent. of people, however, living with lepers develop the disease.

Pathology.—Leprosy bacilli spread through the lymphatics of the corium and subcutaneous tissues, producing granulomata of the skin and infection of lymph

glands; the nasal and buccal mucous membrane, the eye, larynx and internal organs, such as the liver, lungs and testicles, may be similarly involved and bacilli found. The nerves may swell, turn a reddish-grey colour and undergo an axonal degeneration; scanty bacilli may be demonstrated in the endo- and perineurium. Paralysis, muscular atrophy and deformity follow.

Symptoms.—There are three main types of the disease—(1) nodular or cutaneous leprosy; (2) anæsthetic, neural or nerve leprosy; (3) mixed leprosy. The incubation period is uncertain, being 1 to 5 years in most cases, though occasionally persons develop it a few months after coming into an infected area. Often bacilli remain latent for years, and intercurrent disease may be necessary to precipitate clinical leprosy.

1. NODULAR, CUTANEOUS OR LEPROMATOUS LEPROSY.—This is the low resistant type, in which there is gross infection of both skin and nerves; the neural signs are mild, since the invading organisms fail to elicit any marked response from nerve tissue (Muir). Prodromata, which are marked, include leprotic fever, rigors, sweating, progressive weakness, diarrhoea, alternating dryness and hypersecretion of the nasal mucosa and epistaxis. The first positive evidence is the primary exanthem, involving especially the face, buttocks, legs or arms, commencing as a slightly raised erythematous macule which later shows dissociation of sensation and absence of sweating; it may disappear, leaving some brownish discoloration, but soon fever recurs with a fresh eruption, and bacilli may be found in the blood. After one or two recurrences reddish-brown elastic nodules appear, often at the site of the old macular rash, and these may become more generalised. Only the dorsal surfaces of the hands and feet are affected. The face acquires a leonine aspect from the enlarged nose, lobes of the ear and pendulous cheeks. The hair is often lost, especially on the outer third of the eyebrows, the nipples become prominent, the breasts may hypertrophy and the mucous membrane of the nose, pharynx and larynx may be affected. Leprotic nodules often involve the cornea and iris. The further history varies; the nodules may remain stationary, disappear or break down and suppurate. Ulcers may form on the eye, causing blindness, and the larynx and pharynx may be destroyed.

2. ANÆSTHETIC LEPROSY.—This is a highly resistant type, in which the infection of skin and nerves is less, yet the neural signs are more prominent since the reaction in nerve tissue is more marked. Prodromata consist of mental depression, chilliness and malaise with neuralgic pains and paræsthesias, involving the ulnar, peroneal and facial nerves. Numbness of the hands and feet, anæsthesia of ulnar distribution, and maculæ, giving rise to flat, anæsthetic patches resembling ringworm may be the first indications. These anæsthetic patches may commence as erythematous or pigmented or depigmented areas and ultimately become dry and hairless. A quiescent stage may now set in until definite nerve lesions appear. Demonstrable fusiform enlargement, especially of the ulnar and great auricular nerves may develop, and wasting of the hypothenar eminence associated with contraction of the third and fourth fingers is often seen. Muscular palsies and trophic lesions of the skin, nails and bones, including perforating ulcers, are common, and atrophies and contractures like claw hand may ensue. Necrosis or interstitial absorption of the small bones occur, and fingers and toes may disappear. The fifth and seventh cranial nerves are sometimes attacked, and ectropion of the lower lid, followed by corneal ulceration, is common.

3. MIXED LEPROSY.—Many cases ultimately become mixed in type, the nodular and nervous features either developing together or following one another. Tuberculoid leprosy—so called owing to its histological resemblance to tuberculosis—is encountered in patients with a high resistance. The lesions consist of raised plaques or of macules with raised margins: anæsthesia is well marked, and the nerve branch supplying the area is often thickened.

Diagnosis.—Clumps of lepra bacilli which have to be distinguished from tubercle

to appropriate treatment, usually results in defervescence and the disappearance of pus and bacilli from the urine in 7 to 14 days. But some of the cases last many weeks; it is fair to say that this is not seldom due to failure to diagnose the condition, or to employ efficient measures of treatment.

Relapses are very common even when, with chemotherapy, the urine is rendered sterile and the symptoms are relieved. Of complications, *prostatitis* and *epididymitis* are those most often seen; *urethritis* may occur; *pyelonephritis*, especially in young children, may be the precursor of renal failure in later life. It is interesting to record that *epididymitis* may be the first symptom of the disease. This has, in the past, been frequently mistaken for tuberculosis.

(ii) *Recurrent cases*.—A not uncommon type of case is that in which symptoms of acute or of subacute infection occur at intervals over a number of years, the condition of the patient and of the urine being natural between the attacks. Recurring hæmaturia, thought to be due to acute nephritis, to tuberculosis or to calculus, is sometimes due to this condition. The probable source of these re-infections in any individual case is the colon.

(iii) *Chronic cases*.—These are either (a) the sequelæ to acute attacks that have never completely resolved; or (b) they arise insidiously; or (c) they follow instrumental procedures or operations upon the urinary tract; or (d) they complicate mechanical defects, acquired or congenital, such as stricture, enlarged prostate and hydronephrosis; or (e) they occur as secondary infections in cases of renal or vesical calculus or of tuberculosis.

The symptoms in these chronic cases vary greatly. In one group it is the general toxic state that is the main feature—a sallow complexion, loss of tone, a low blood pressure, colon dyspepsia, anæmia, headache and backache. In another group the local symptoms predominate—increased frequency of micturition, which may be extremely trying, pain during or after the act, and referred pain and discomfort in the vesical zone. In a third group there is little or no interference with health, general or local. The importance of chronic polynephritis as a cause of hypertension has only recently become apparent.

The urine in chronic infections shows as much variety as do the symptoms. The characteristic "fishy" odour is rarely absent; the reaction is generally acid, but infection by *Proteus* renders the urine strongly alkaline; the amount of pus present may be very little or may be considerable, but the degree to which the patient is troubled by no means corresponds to the degree of pyuria; mucus is in excess; bacilli are constant and, like the pus, are very variable in quantity. Hæmaturia is uncommon in chronic infections, but it is easily induced by instrumental investigation, as are also "flares-up", of the chronic state, with the production of rigors, high fever, severe malaise and oliguria. For this reason, methods of differential diagnosis which do not involve instrumentation should be employed before the patient is subjected to cystoscopy or ureteric catheterisation. Diagnosis rests upon the isolation of the organism from a clean specimen of urine. Of particular importance is the differentiation of the condition known as abacterial pyuria—a subacute illness characterised by pyuria, frequency of micturition and strangury, which yields rapidly to intravenous injection of neo-arsphenamine.

BACILLURIA.—This term is properly applied to a urine which is loaded with bacilli, but in which there is no pus, or, at most, a few leucocytes seen on microscopic examination. It is usually of short duration. The appearance of the urine is characteristic: shimmering when agitated and viewed by transmitted light. The smell already referred to as so typical of colon bacillus urinary infections is usually present here also.

OTHER SITES OF COLIFORM BACILLUS INFECTION.

(1) *The uterus and Fallopian tubes* are sometimes the site of infection, as in puerperal sepsis; but the infection is then usually a mixed one, with streptococci.

(ii) Some situations quite remote from the bowel are now and again infected by coliform bacilli—the *middle ear*, the *pleura*, the *bronchial tract*, *bones* and *joints*. Infection of the middle ear occurs as the result of impure water in swimming-baths.

Bact coli septicæmia, unless it occurs as a terminal event, in which form it is not at all uncommon, is rare. When it does occur, however, it is by no means always fatal. Septic endocarditis, due to coliform bacilli, is rarer still.

Treatment.—Only the treatment of coliform bacillus infection of the urinary tract is of present relevance, the therapeutic problem with infection in other sites is commonly surgical.

The principles of treatment are simple. to determine the sensitivity of the infecting organism to the various chemotherapeutic and antibiotic agents, and to administer, in an attempt to sterilise the urine, the drug thus shown to be most suitable, to correct, where necessary, any mechanical defects in the urinary tract or other abnormalities which may have led to infection.

General measures depend upon the severity of constitutional symptoms. In acute infections the patient is confined to bed and encouraged to drink 4 to 5 pints of fluid in the 24 hours. Sufficient sodium bicarbonate and potassium citrate to make the urine alkaline will relieve strangury.

A catheter or "mid-stream" specimen of urine should be sent to the laboratory for isolation of the infecting organism and tests of its sensitivity. Treatment with sulphonamide (see p 24) should be started immediately this has been done, without awaiting the pathologist's report. The great majority of these infections respond rapidly to sulphonamide, if the report later shows it to be unsuitable, a change should then be made to the drug to which the organism is most sensitive. Treatment should continue until the urine has been sterile for 4 days.

In more chronic cases it is justifiable to await the result of sensitivity tests, although time may be saved by administering sulphonamide immediately the specimen has been taken.

Particularly in chronic or recurrent cases, the possibility of some mechanical defect in the urinary tract must be considered. These include enlargement of the prostate, calculus, hydronephrosis, cystocele, stricture and various congenital anomalies. Intravenous pyelography, cystoscopy and ureteric catheterisation may be required for their demonstration and treatment will include their correction where possible.

Chemotherapy and the antibiotics have proved so effective in treatment, that the various adjuvant measures, previously deemed necessary, have faded into unimportance. It is true that the bowel must be the source of all coliform bacillus infection, but the path followed by the organism is uncertain and the association with colonic disease uncommon. If such an association is noted, the disease or disorder of the colon must be treated on its merits.

TYPHOID FEVER

Synonyms —Enteric Fever, Gastric Fever, Typhus Abdominalis

Definition —An infectious fever characterised by pyrexia of continued type, an eruption, in crops, of rose spots, enlargement of the spleen, abdominal tumidity and bowel disturbance. Ulceration of the small intestine and enlargement of the mesenteric lymph glands and spleen are distinctive lesions.

Typhoid is a septicæmia caused by ingestion of the *Salmonella typhi* of Eberth, which is absorbed by the lymphatics of the small intestine and carried to all parts of the body, it settles in the agminate glands (Peyer's patches) of the intestine, the mesenteric lymph glands, spleen, liver, gall-bladder and bone-marrow. Those organs which have excretory ducts, e.g. the liver and gall-bladder and the kidneys, as well as the intestinal tract, form the chief channels of elimination.

150 mg daily, this drug has been used successfully as an alternative in individuals who are intolerant to sulphones

Lepra reaction should be treated with diaphoretics such as aspirin, phenacetin hot drinks and calcium and alkalis in large doses. In nerve leprosy the agonising pain may be relieved by adrenaline intramuscularly or ephedrine given orally or by infiltration of the nerve. Vitamin B₁₂ given by intramuscular injection and by the mouth, in large doses may lead to disappearance of neuritic pain, and a diminution in the tenderness and swelling of the nerves.

Potassium iodide is a dangerous drug, but Muir uses it in the late stages of treatment when the resistance is high and the case has become bacteria free. Diathermy is of value in subacute and chronic nerve lesions. If the ulnar nerve is bound down to bone—especially at the elbow—freeing adhesions and linear incision of the sheath with or without removal of fibrous tissue may bring relief. Abscesses occurring in the ulnar or other nerves should be incised, drainage is rarely needed.

N HAMILTON FAIRLEY

COLIFORM BACILLUS INFECTIONS

The coliform group has been expanded to include, in addition to the original *Bacterium coli* and *Salmonella typhi*, the organisms of bacillary dysentery (*Shigella dysenteriae*) of the paratyphoid fevers (*Salm. paratyphi*) and those responsible for some cases of food poisoning such as *Salm. enteritidis*, *typhi murium*, *cholera suis* and others. Here, infections for which *Bact. coli* is responsible are alone considered, but there are many strains of the organism which differ among themselves in pathogenicity, virulence and cultural behaviour.

MODES OF INFECTION—In health, coliform bacilli are confined to the intestine. The modes of infection of parts of the body other than the bowel are at times very apparent at others obscure. Of any particular tissue there are three possible routes of infection: (1) The *direct* route, that is, by the immediate transference from the bowel to the infected area, (2) by the *lymphatics* and (3) by the *blood stream*. In some infections e.g. of the gall bladder, pericolic tissues, pelvic cellular tissue, etc. the direct route is no doubt the one generally followed. Of the two indirect routes however some doubt exists as to the more likely one in certain cases, such as infection of the urinary tract especially, in some instances of this latter important condition it is clear that invasion takes place again directly, through the urethra. The cystitis which still occasionally follows the use of the catheter illustrates this, and the greater frequency of cystitis in girls than in boys at the napkin age has been adduced in favour of this route. In the acute pyelitis complicating or following typhoid fever, it is highly probable though not certain that infection proceeds via the blood stream to the kidney, and thus to the pelvis. But in those acute primary infections of the urinary tract, which are so common in both sexes the mode of entry of the bacillus of the kidney pelvis is problematical.

SITES OF INFECTION—The sites of infection by coliform bacilli are very numerous. Mention will only be made here of those which form the basis of important disease processes which demand recognition and treatment in practice.

1 The *bowel* itself may be the site of infection. This may take place (a) because the infecting strain of coliform bacillus has absolute pathogenic qualities, or (b) because the virulence of one or more of the usually saprophytic strains is increased, or (c) because the resistance of the mucosa is lowered by chemical or physical changes or by infection by another pathogenic microbe. From one or more of these factors acute gastro enteritis, enteritis or entero colitis may ensue. Poisoning by *Salm. enteritidis* the result of eating contaminated food is an important instance of (a) and perhaps also of (a) combined with (c). Atypical coliform bacilli are often isolated from the stools of patients with acute gastro enteritis, but their importance as a cause

of this disease remains problematical, except in certain cases in infants where their ætiological role has been established

2 *Gall-bladder sepsis* is closely associated with coliform bacillus infection. It is commonly held that infection of the gall-bladder by this microbe is one of the important factors in the evolution of cholelithiasis. However this may be, it is certain that coliform bacilli are frequent infecting agents in *cholecystitis*, both acute and chronic. The fact harmonises with the known frequency of gall-bladder infection during typhoid fever.

3 *Appendix inflammations, diverticulitis, pericolic suppuration* and local peritonitis complicating intestinal conditions, are all of them associated with coliform bacillus infection, and in many instances with this alone.

4 The *urinary tract* is infected with great frequency, with how great frequency we are only now realising, as the result of systematic cultivation of the urine in doubtful cases of the condition, and in obscure cases of illness in which no such condition is at first suspected. The presence of coliform bacilli in the urine may derive from the discharge of an infective focus adjacent to the urinary tract, in the prostate, urethra or pericolic tissues, or may be due to true infection of the urinary tract itself, *pyelitis*, *pyelonephritis* or *cystitis*. Concerning the former, no more need be said in this place.

COLIFORM BACILLUS INFECTION OF THE URINARY TRACT—The cases met with may be conveniently described as falling into three groups.

(i) *Acute cases*—In the majority of these cases the infection appears to arise in the pelvis of the kidney, some are undoubtedly vesical in origin, in not a few it is uncertain where the infection begins. The disease is at times fulminating in its acuteness, being ushered in by rigors, high fever (103° to 105° F), delirium and great drowsiness. More often the symptoms are abrupt and severe, but not alarming. There may be pain and tenderness in the loin, though both may be absent, and one or other kidney may be tender under bimanual examination. But in more cases than not there is a striking absence of both physical signs and focal symptoms, so that, unless the existence of the disease is borne in mind, and the urine is examined carefully, the patient is thought to be suffering from "influenza."

In those cases in which the bladder is, from the first, markedly affected, symptoms of *dysuria* are present—frequency, pain and strangury. Such symptoms draw attention of course, to the nature of the process.

The *urine* shows a great range of variations in its features. There may be a frank *hæmaturia*, a fact which is not so widely known as it should be. Coliform bacillus infection is the explanation of a large number of obscure cases of *hæmaturia*. The amount of pus is very variable—it may be very considerable, or it may be represented only by leucocytes seen on microscopic examination. In very severe cases portions of the bladder mucosa may be shed in the form of sloughs, but this is uncommon. The number of bacilli present in the urine varies greatly, in some cases they are so abundant as to constitute by far the greater part of the total sediment. The colour and amount of the urine depend upon the degree of pyrexia and the amount of fluid ingested. Constipation is the rule, the tongue is generally covered by a creamy fur and anorexia is common. As in so many acute coliform bacillus infections, the mental state tends to depression.

The disease is often a strikingly dramatic one in children, it is one of the few conditions which may be associated with a rigor, and there is a maximum of febrile reaction with lassitude and even stupor, and a minimum of serious effect upon the vital organs. It is not very uncommon to see a temperature of 105° or 106° F, with big intermissions, the child is very ill during the pyrexial stage and comparatively well when the temperature falls. Marked drowsiness, even stupor, may occur, such a condition, indeed, should raise a suspicion of this infection in the absence of signs of meningitis. The disease is not very uncommon even in babies.

The course of the disease varies much. Prompt recognition of its nature, leading

Ætiology.—*Salm typhi* is a flagellated rod-shaped, Gram-negative organism, about 3μ in length and 0.6μ in thickness. It is actively motile and easily grown on artificial media. It belongs to the enteric group of organisms, a group which includes also the paratyphoid bacilli (*Salm paratyphi*). It grows best at blood heat and is quickly killed by boiling water, and within 15 minutes by exposure to a temperature of 60°C (140°F). It may survive for a considerable time in ice, and also for some days in fresh or salt water. It resists drying, so that typhoid may also be propagated by dust or by articles soiled by typhoid excreta. It has been found alive in the mantle-cavity and intestines of oysters, mussels and other shell-fish which have lived in sewage-contaminated water. It multiplies freely in butter and in milk, and may survive in unripened cheese.

The toxins are mainly intracellular. Inoculation of animals produces a septicæmia without the intestinal lesions seen in man. Even in the latter the disease at times occurs without producing intestinal ulcers. The serum of those infected has a specific agglutinative influence on cultures of the organism, a fact which is made use of in diagnosis, and at certain stages the bacillus can be cultivated from the blood, bone-marrow and bile. In man, infection is introduced by the alimentary tract, and is derived, directly or indirectly, from a human source, man being the only reservoir of the disease. Typhoid bacilli can be differentiated into types by the use of specific Vi bacteriophages, a useful measure in tracing sources of infection.

Typhoid occurs in all parts of the world, but is most rife in tropical and sub-tropical countries. In Great Britain it is most prevalent in the months of September, October and November, in other countries the maximum incidence corresponds to the warm season. A hot, dry summer increases the prevalence in the autumn. An epidemic recrudescence is believed to occur every 5 or 7 years. Rather more males than females are attacked, and the greatest susceptibility is between the twentieth and twenty-fourth years. Infants are rarely infected. After the thirtieth year there is a progressive fall in its incidence. It is rare but not unknown in old age.

One attack confers immunity, which usually lasts for life, but second and third attacks have been reported. Where typhoid is endemic a proportion of the community acquires immunity without having passed through a recognisable attack. The supposed racial immunity of certain peoples may in reality be acquired through infection contracted in childhood. Fatigue and overwork are favouring factors, and no condition predisposes so much as does war to typhoid and paratyphoid infections, owing to the aggregation of susceptible subjects under conditions of defective sanitation, fatigue and exhaustion. Prophylactic vaccination has found its greatest triumphs under these conditions.

Propagation is from the human source and may be indirect or direct. Of indirect causes aerial infection, apart from the influence of wind-borne dust and of flies, is very doubtful. Drinking water supplies contaminated by sewage or by the excretions of a carrier are the most common cause of widespread outbreaks. Milk, ice cream, unripened cheese, butter and other articles of food may also act as local diffusers of infection. Celery, watercress and other green vegetables, eaten uncooked, also spread the disease. Of shell fish, oysters, mussels, cockles and periwinkles are dangerous. Fomites, enema syringes, bedpans, etc., which have been soiled by typhoid excreta undoubtedly act as infective agents. Laboratory workers have been infected by their cultures.

Of convalescents from typhoid, a small proportion, about 5 per cent., continue to pass bacilli, often intermittently, in the stools for months or years. These are known as intestinal carriers. They may appear to be quite healthy, or may suffer from periodic intestinal disturbance or from symptoms referable to the gall-bladder. Typhoid bacilluria occurs in perhaps 25 per cent. of the cases of typhoid, but is, as a rule, quite transitory, urinary carriers being much less common but possibly more dangerous than intestinal carriers. Carriers are particularly dangerous when they happen to be engaged in handling food, milk or water supplies.

The endemic occurrence of typhoid in certain localities is now attributed to the influence of human carriers rather than to the persistence of infection in the soil, although it is an undoubted fact that the typhoid bacillus may persist for a time and even multiply in sewage-infected earth.

Pathology.—The portal of infection is the intestinal lymphatic system. The bacilli multiply in the liver, spleen and mesenteric lymph glands during the incubation period. A bacteræmia initiates the clinical onset and excretion in the bile soon follows. It is now, contrary to former conceptions, held that the Peyer's patches are not involved until the septicæmic stage.

The characteristic lesions are in the small intestine. Proliferation of the large mononuclear phagocytes of the reticulo-endothelial system is the distinctive reaction. In the early stages the Peyer's patches are swollen, the swelling attaining its height about the tenth day of the disease. The solitary follicles of the intestine are similarly affected and a diffuse catarrh of the whole intestinal tract, including the stomach, may be present. Necrosis ensues in the lymphoid masses, and sloughs are formed, the separation of which occurs during the third and part of the fourth weeks. In some cases, resolution may take place without necrosis. The ulcers are ovoid and lie along the long axis of the bowels. Those which arise in the solitary follicles are more circular. The edges of a recent ulcer are undermined, and the floor shows smooth muscular fibres, or the peritoneal coat. Perforation or hæmorrhage may ensue. Immediately above the ileo-cæcal valve sinuous tracts of ulceration may be evident. Ulceration of the large intestine is rare. The ulcers heal without contraction in a week or 10 days. Their inflamed bases very rarely give rise to peritoneal adhesions or bands. When perforation occurs it is usually in the lower ileum, where ulceration is most intense. It may, however, happen in other situations.

The mesenteric lymph-glands are inflamed, but rarely suppurate. The spleen is swollen, soft and cherry red, an acute reticulo-endothelial hyperplasia being present. Splenic infarction may occur, but rupture is rare. The liver presents a parenchymatous degeneration with minute areas of focal necrosis which originate in clumps of macrophages lying in the blood sinuses. Similar foci (*typhoid nodules*) may be found in the spleen and in the bone-marrow. Infection of the gall-bladder may occur with subsequent formation of gall-stones. Pylephlebitis is a rare complication. Cloudy swelling of the kidneys is the rule. In chronic urinary carriers inflammation of the renal pelvis or urinary bladder may be found.

The myocardium undergoes fatty and granular degeneration. Hypostatic congestion of the lung bases is the rule with, it may be, distinct broncho-pneumonic consolidation. Gangrene, abscess or infarction of the lungs is rare. Ulceration of the larynx may occur, the ulcers being found in the neighbourhood of the arytenoid cartilages, or at the base of the epiglottis. Necrosis of the cartilages sometimes ensues. Zenker's vitreous degeneration of muscle is particularly marked. It affects the straight muscles of the abdomen, the adductors of the thigh and the diaphragm; rupture of muscle and hæmorrhage may result. Osteo-periostitis of the tibia, vertebrae and other bones may be due to infection with the typhoid bacillus or to secondary invaders. Superficial abscesses, degenerative changes in the central nervous system or peripheral nerves, and venous thrombosis are also possible sequels of typhoid infection.

Symptoms and Course.—The period of *incubation* averages from 10 to 14 days, but may be as short as 3 days or as long as 3 weeks. During this period symptoms are generally absent, but ill-defined malaise or, more rarely, gastro-intestinal disturbance may occur.

The *onset* is generally insidious with chilliness, lassitude, loss of appetite and muscular pains. Symptoms which are particularly suggestive are frontal headache, oozing epistaxis, slight bronchitis and disturbing dreams. The tongue becomes furred, and the mouth dry. The hearing often becomes less acute and a brightness of eye may be noticeable. The bowels are loose or constipated. The patient may not take to bed for a day or two. The temperature mounts gradually, being a degree or more higher each succeeding night with morning remissions. By the end of the first week the clinical condition is characteristic. The aspect is heavy and the cheeks are flushed. The lips and mouth are dry, and the dorsum of the tongue covered with a dirty white fur, the tip and edges being raw. The abdomen is slightly tumid, with gurgling in the right iliac fossa. The bowels are perhaps loose, several liquid motions like pea soup being passed in the 24 hours; sometimes, however, there is constipation. The spleen may already be palpable. A characteristic feature is a moderately full but easily compressible pulse, the frequency of which is not increased in proportion to the temperature. The respiration is accelerated. The temperature will by now have attained a maximum of 103° to 105° F., still showing morning remissions of about 1° , and is unstable, reacting quickly to minor disturbances. The urine is high coloured and concentrated, and the skin usually dry. Thirst and headache are the chief complaints.

The rose spots usually make their appearance towards the end of the first week, sometimes on the fifth day, more often between the seventh and twelfth. Each spot is a circular, slightly elevated papule of a pale pink colour from 2 to 4 mm. in diameter, disappearing on pressure. The rash should be sought for on the abdomen, the flanks, the sides of the chest and the back. The spots appear in successive crops, each one fading in 3 or 4 days, and leaving a transitory brownish stain. Often the eruption is scanty, a few spots only being seen; occasionally it is very profuse, and involves the limbs as well as the trunk. The face usually escapes. Minute sudaminal vesicles occasionally cap some of the spots. The eruptive period lasts from 10 days to 3 weeks. A profuse rash does not necessarily indicate a severe attack. The spots are due to bacterial embolisms.

By the second week the fever has reached its fastigium. The temperature maintains its level with slight morning remissions, the headache may abate, but prostration increases and the other symptoms are more severe. The lips become cracked, sordes accumulate on the teeth, the abdomen becomes more distended and diarrhoea is often a marked feature, the stools being liquid, yellow in colour, alkaline and foul. They may be chocolate-coloured or red from admixed blood and small shreds of tissue, or actual sloughs may already be present. The evacuations are not accompanied by colic or tenesmus. The spleen is now larger. The pulse-rate will have quickened to a frequency of 112 to 140. It is often dicrotic, and the heart sounds enfeebled. The bases of the lungs may now show signs of hypostatic congestion, and the respiration be more accelerated with slight lividity of the lips and face. The initial headache is replaced by delirium of a muttering character, and muscular wasting is rapid. The urine may be albuminous and scanty. Patients may succumb during this period from toxæmia, or towards the end of the second week from perforation of the bowel or intestinal hæmorrhage.

During the third week improvement should occur, the temperature becoming more remittent in type, the morning reading falling more rapidly than that of the evening. The tongue cleans and appetite begins to return. During the fourth week defervescence may be completed, the temperature usually remaining at a subnormal level for some time. In severe infections, however, the third week is a period of

increasing anxiety. The symptoms increase in severity and the patient may pass into the "typhoid state", lying on the back in a semi stuporous condition. The pulse and heart sounds become more and more enfeebled, the pulmonary congestion increases, the extremities become blue and cold, subsultus tendinum appears, and the evacuations are passed unconsciously. Sometimes there is retention of urine. Extreme abdominal distension may supervene, and the occurrence of perforative peritonitis or of hæmorrhage from the bowel is more than ever to be dreaded. In such severe cases the fever may be prolonged through the fourth and fifth weeks before any signs of defervescence appear. They are not necessarily fatal.

Convalescence after a severe attack is always protracted. The temperature is at first subnormal, and remains in a very unstable state. The heart sounds remain enfeebled, and the pulse is often rather fast or easily quickened by exertion or excitement. The effort of standing and walking is difficult and painful. The appetite, however, is good, and the weight rapidly increases. The aspect gradually becomes less ætæmic. Slight peeling of the skin, loss of hair and ridging or furrowing of the nails is often noticeable. During this period the feet and ankles may show slight œdema, and cutaneous abscesses or localised bone abscesses may occur. Thrombosis may appear in the veins of the calf or thigh, it is the chief complication of early convalescence.

Relapse—Tendency to relapse is a marked feature of typhoid fever, and shows itself in from 5 to 15 per cent of the cases. The relapse may occur during actual defervescence, but more commonly develops after an afebrile period of a week or a little longer. The symptoms are a repetition of those of the original attack, but in a mitigated form, the fever reaching its acme in a shorter time, and the whole duration being 10 days or a fortnight. The spleen enlarges again, a new crop of rose spots usually appears, fresh ulceration of the bowel occurs and blood culture may again prove positive. On occasions, the relapse equals or exceeds the original attack in severity, and may even prove fatal. Second and third relapses are not unknown. Spurious relapses are recrudescences of fever during convalescence, of short duration and unaccompanied by definite symptoms. Their explanation is often obscure.

VARIETIES—The fact that typhoid fever may show great variations in its clinical characters and in the severity and prominence of different symptoms has led to the description of many special types. Different epidemics may differ much in their salient features.

Variations in onset—The onset of symptoms is sometimes sudden, it may be with rigors and vomiting. The temperature rises quickly, and delirium may supervene early. In such cases, death may occur during the second week, or the disease may gradually assume the ordinary type. In exceptional cases, severe bronchitis or pneumonia may mark and mask the onset, and the true nature of the infection may be overlooked. The prominence of meningeal symptoms may lead to confusion with cerebrospinal fever, and the differential diagnosis only be possible by examination of the cerebrospinal fluid. If typhoid meningitis is present, lymphocytes or polymorphs predominate, according to the severity of the infection and the typhoid bacillus grows on culture. More commonly the condition is better described as meningismus: the fluid is under tension but clear, it is sterile and the symptoms quickly subside after lumbar puncture, to be succeeded by the more typical signs of typhoid fever (see also p. 61). Yet another occasional mode of onset is with a primary acute hæmorrhagic nephritis. When acute gastro intestinal symptoms signalise the invasion, appendicitis or irritant poisoning may be simulated. An onset with faucial angina sometimes occurs.

The terms *pneumo typhoid*, *meningo typhoid* and *nephro typhoid* have been used to designate some of the above mentioned types.

Variations in course—There is an ambulatory form in which febrile disturbance is generally slight, and the patient continues about during the whole or the greater

part of the illness. Some such cases end in recovery, but others run a very severe course, the patient taking to bed about the end of the second week with aggravated symptoms, or succumbing to hæmorrhage from the bowel, perforation, acute delirium or circulatory failure. Mild and abortive forms of typhoid also occur in which the fever is insignificant, or, after a well-marked onset, ends in a rapid defervescence between the eighth and fourteenth day. An afebrile form is known to occur in the enfeebled or those exposed to great hardships.

Variations due to age, pregnancy and other causes—Typhoid fever is rare in infancy, but becomes more frequent in childhood, and then, generally, the symptoms are mild, the pyrexia of short duration and sometimes of a markedly intermittent or remittent type. A primary bronchitis or gastro-enteritis may be simulated. Such complications as perforation or hæmorrhages are rare.

In the aged, particularly in those over 60, typhoid tends to run an unfavourable course, hypostatic pneumonia and circulatory failure being common.

Abortion or premature delivery takes place in from 50 to 70 per cent. of pregnant women who contract typhoid. The fetus is dead or, if born alive, usually succumbs to an acute typhoid septicæmia. The prognosis as regards the mother is not especially influenced.

In malarial patients the onset of typhoid may be sudden, with a typical rigor, but the severe symptoms proper to typhoid develop later. On the other hand, subtertian malaria may closely simulate typhoid in its commencement.

Chronic alcoholism exerts a very unfavourable influence. Pre-existing pulmonary tuberculosis is apt to advance rapidly during convalescence from the fever. In diabetics typhoid often runs a mild course.

Special Symptoms and Complications—*Digestive system*—*Suppurative parotitis* is attributed to duct infection, and occasionally leads to cellulitis. Attention to the cleansing of the mouth goes far to prevent it. Ulcers sometimes appear on the pillars of the fauces and the pharyngeal wall (*Duguet's ulcerations*). Diarrhoea is not a constant feature, some patients being constipated throughout the disease. The diarrhoea often disappears after a few days' dieting and hospital treatment, but in grave infections it may be severe and persistent.

Meteorism with a distended, tense, tympanitic abdomen signifies a virulent infection. It may or may not be accompanied by severe diarrhoea, and is often a harbinger of hæmorrhage or perforation.

The incidence of intestinal hæmorrhage, sufficiently gross to be detected by inspection of the stools, varies in different reports from 5 to 20 per cent. of all cases. It is most common at the time when the sloughs are separating, i.e. at the end of the second or beginning of the third week. The hæmorrhage may be slight, but more often is profuse. The evacuated blood is bright red in colour, unless it has been retained in the bowel. The signs of a severe hæmorrhage are a sharp fall in the temperature, a sensation of lamininess, increased frequency of the pulse and, it may be, a transient rise in blood pressure with disappearance of diastolic pressure. The spleen may shrink rapidly. Sometimes the hæmorrhage is fatal before any blood is voided.

There is also a hæmorrhagic form of typhoid in which melæna may be an early sign, associated with petechiæ or bruises in the skin and hæmaturia. The outlook, then, is very grave.

Perforation of the bowel causes one out of every 3 or 4 deaths. Its incidence is something under 5 per cent. It is commonest towards the end of the second or in the third week especially, but not at all exclusively, in cases characterised by severe diarrhoea or by meteorism. Its onset may be preceded by intestinal hæmorrhage. The perforation generally lies within the last 12 in. of the ileum, but may occur elsewhere. Shivering, with sharp pain in the hypogastric region is usually the first sign, but the onset may be quite insidious. Localised tenderness, localised rigidity and local immobility of the abdominal wall accompany the pain. The temperature

may show a sudden drop to subnormal followed by a rise; but sometimes no variation is detected. Both pulse and respiration rates are usually increased, and the former should be watched carefully. Obliteration of the liver dulness is especially significant when occurring in a rigid and retracted belly. Irritability of the bladder and rectal tenesmus may occur when a perforated coil lies in the pelvis. More reliance should be based on the local than on the general symptoms in making the diagnosis. After the first shock the patient may react and show deceptive signs of improvement, but before many hours the signs of spreading peritonitis will assert themselves. A polynuclear leucocytosis generally accompanies perforation, but is inconstant and not of great diagnostic value.

There are other causes of abdominal pain in typhoid fever, such as acute cholecystitis, suppurative cholangitis, portal pyæmia, suppurating mesenteric glands, appendicitis and splenic infarction, but none of these is common. Thrombosis of the iliac veins may also cause abdominal pain and tenderness; a clue to this condition may often be found by examining the veins of the lower limbs and by looking for slight œdema of the leg or foot.

A transient hepatitis sometimes occurs, but jaundice is rare. Gall-stones are a recognised sequel of typhoid infection and may contain the bacilli.

Respiratory system.—A mild bronchitis is present in most cases. In severe infections, hypostatic congestion of the lung bases occurs. Lobar pneumonia may supervene in the third or fourth weeks of the disease. Although typhoid bacilli may occur in the sputum, and be found in the lung, pneumococci are also present; the condition may be overlooked, as cough is often slight and rusty sputa absent. Embolic and pyæmic processes in the lungs during typhoid may give rise to abscess, gangrene and pneumothorax. Intra-pulmonary thrombosis, with infarction, is a very rare event.

Ulceration of the larynx is not infrequent in severe cases. It involves the post-arytenoid region and has been likened to a pressure sore. It may be latent or give rise to huskiness of the voice, stridor and toneless cough. There may be pain on deglutition and laryngeal tenderness. The slighter symptoms may abate, but sometimes the process terminates in necrosis of cartilage and œdema or stenosis of the larynx.

Blood and circulatory system.—A slight polynuclear leucocytosis is sometimes seen in the first week of infection. More characteristic is anæmia associated with leucopenia, a characteristic absence of eosinophils with a relative increase in the lymphocytes and large mononuclear cells. In uncomplicated typhoid fever the leucocyte count rarely exceeds 6000. The eosinophils reappear with convalescence. The appearance of a polynuclear leucocytosis indicates the onset of inflammatory complications.

Circulatory failure is a feature of severe attacks. The pulse-rate, usually but moderately accelerated in typhoid, rises to 120 or more, dicrotism disappears, the cardiac sounds weaken and the blood pressure falls. Acute collapse, with sudden drop of temperature, coldness of the skin, cyanosis and feeble or irregular pulse, may ensue. The collapse may be recovered from, but its occurrence is ominous.

Femoral thrombosis is apt to occur during early convalescence. It is usually left-sided, and may commence in the veins of the calf, popliteal space or in the internal saphenous trunk. The symptoms are pain and tenderness at the site of the thrombosis, with fever, tachycardia, and later, swelling of the limb, usually moderate in degree. The affected vein may often be felt as a tender spot or cord. In a few weeks the thrombus is absorbed, and the circulation re-established, but sometimes permanent obstruction and œdema result. The clot, if dislodged, may cause pulmonary embolism.

Arteritis, leading to occlusion, is an uncommon complication. The vessels affected are those of the lower limbs, sometimes those of the upper extremities, neck or brain.

Urinary system.—Febrile albuminuria is often present, but is transitory. Typhoid

bacilluria occurs in some cases, the urine presenting a slightly turbid, opalescent appearance, but a similar appearance may be due to the colon bacillus. Symptoms of pyelitis, pyelo-nephritis or cystitis may supervene. Urinary carriers continue to discharge typhoid bacilli for long periods. Acute nephritis is uncommon, it may occur either at the commencement or height of the disease. Retention of the urine may supervene during typhoid, but suppression is rare. During the fever the excretion of urea and of uric acid is increased, but the chlorides are diminished. A moderate-oliguria is the rule. A considerable reduction, in spite of free fluid intake, is evidence of a severe attack. Polyuria occurs at the onset of convalescence, and is of good omen.

Generative system—Orchitis and prostatitis have been observed. In females vulvitis and also mastitis may occur.

Nervous system—Meningeal symptoms at the onset have already been mentioned (p 101). Rarely meningitis occurs in a purulent form during the third or fourth week of the disease. Its mortality is high (50 to 100 per cent). Delirium is often present at the height of typhoid fever and is usually of a quiet type. Drinkers may develop delirium tremens. Convulsions are rare. They may occur at the onset, or when occurring later may be due to cerebral thrombosis, encephalitis or meningitis. Multiple neuritis or neuritis of such nerves as the ulnar or peroneal may supervene, in the latter cases often due to pressure. Acute tenderness of the toes during convalescence is also attributed to neuritis. These polyneuritic phenomena are far less common when careful attention is paid to the patient's diet, they probably result from vitamin deficiency. During the course of the fever hemiplegia or aphasia may supervene.

Mental disturbance is occasionally a sequel, taking the form of mania, melancholia or dementia. For many months after a severe attack the patient may remain in a fatuous condition but ultimately recover.

As regards the special senses, temporary deafness is characteristic of the fever, and sometimes suppurative otitis occurs. Double optic neuritis is a rare complication which may lead to blindness.

Osseous and muscular systems—During convalescence localised osteo periostitis of the tibia, sometimes of the femur, ribs or other bones may appear. It may terminate in suppuration with limited necrosis. The inflammation is chronic and relapsing. Typhoid bacilli may persist in the pus for long periods. A painful inflammatory affection of the ligaments, intervertebral disks and vertebral periosteum is the basis of the "typhoid spine". The lumbar and sacral regions are chiefly involved, with stiffness and pain on movement. The condition is chronic, but the ultimate outlook is said to be good. Arthritis of large joints is a rare occurrence, it may lead to dislocation of the hip.

Rupture of the rectus abdominis, sometimes of the adductors or other muscles, may take place. This is accompanied by local hæmorrhage. The resulting fluctuating and discoloured swelling may clear up or go on to suppuration.

Cutaneous system—Abscesses and boils may prove troublesome. Linear atrophicæ tend to form in the skin of the abdomen and thighs. In severe cases pressure sores may form on the sacrum, the heels or other pressure points. These bed sores are a source of danger from septicæmia or pyæmia.

Diagnosis—Of the symptoms of onset, headache, slight epistaxis, disturbed sleep, a mild degree of bronchitis, abdominal uneasiness and some disturbance of the action of the bowels are very suggestive. Gradual daily increase in the pyrexia and its maintenance after the lapse of a week at a steady level of 103° or 104° F, with slight morning remissions, is significant. Relative slowness of the pulse and the presence of dirotism are additional diagnostic points. The dry furred tongue peeling in lateral and central strips, slightly tumid abdomen, moderately enlarged spleen and the appearance of rose spots are confirmatory. The abdominal reflexes are often absent.

SPECIAL DIAGNOSTIC METHODS—1 *Blood examination*—Culture is particularly valuable in the first week before the agglutinative reaction has appeared or the rose spots are evident, but is also applicable during the second and third weeks and in relapse. Ten to 20 ml of blood drawn aseptically from a vein at the bend of the elbow are allowed to run directly into plenty of broth or peptone solution or, better, into a medium which contains filtered bile or bile salts. At the same time a blood count should show a characteristic leucopenia with a relative lymphocytosis.

2 *Cultures from bone marrow* obtained by sternal puncture are said to be more often and more persistently positive than blood cultures.

3 *Cultures from the stools*—Owing to the presence of other intestinal bacteria this is not always an easy process, but by enrichment methods and the use of litmus-lactose agar, or MacConkey's medium or the bismuth sulphite medium of Wilson and Blair, bacilli have occasionally been found during the incubation stage and in about 50 per cent of the cases examined in the first week, a proportion which increases in the third week. Stool culture is also of value for the detection of intestinal carriers, and for determining whether a convalescent is fit to mix with other members of the community. The discharge of bacilli often being intermittent, more than one examination is necessary.

4 *Cultures from the bile*—In suitable cases these may be obtained from bile removed by duodenal siphonage with the Rehfuss tube. The results of bile culture, like those of bone marrow culture, are more persistently positive than blood cultures and are especially valuable in obscure, subsiding and relapsing infections.

5 *Cultures from the urine*—The typhoid bacillus hardly ever appears in the urine before the tenth day, and, as a rule, not before the fifteenth. The infected urine is generally opalescent and slightly albuminous. Cultures are made without difficulty and are useful not only for diagnosis but also for the detection of urinary carriers.

6 *Agglutination tests*—Towards the end of the first week of typhoid fever the blood serum begins to agglutinate the typhoid bacillus. This power reaches its maximum about the eighteenth to the twenty-third day. The test is performed with standardised suspensions and repeated every 4 or 5 days. An agglutination titre of 1:128 is regarded as positive. Normal blood rarely shows an agglutination higher than 1:64. Rising titres are highly diagnostic. Dreyer standard suspensions, being formalised, produce H or flagellar agglutination mainly. This is specific in the case of *Salmonella typhi* and *paratyphi A*. *Salmonella paratyphi B*, however, may occur either in the specific or in the group phase, and in the latter case possesses agglutinative elements which are common to other members of the *Salmonella* Group and so its antiserum may agglutinate these organisms.

A second agglutinin, known as O or somatic, should be investigated at the same time. The actual titres obtained with this usually are less than those obtained with H. An O agglutination is also possible with other members of the *Salmonella* Group, so O agglutination is not so specific as H.

A third agglutinin, known as the Vi, appears early and is usually transitory. It affords strong evidence of recent infection. In chronic typhoid carriers it persists and is said to be of value in their detection.

As a continued fever of the enteric type may, although rarely, be caused by other members of the *Salmonella* Group, it is now customary to employ formalised suspensions not only of *Salmonella paratyphi B*, H specific, but also of it or some other member of the family in the group phase.

T.A.B. vaccine, in consequence of its mode of preparation, evokes H agglutinins chiefly, and these may persist for some years. The appearance of O agglutinins in an inoculated person shows an enteric infection. Blood culture or examination of the excreta may reveal its identity. A rising titre of H agglutination for a particular organism may also do this, but it is known that other, quite different, infections may also raise the H titre (*anamnetic reaction*).

DIFFERENTIAL DIAGNOSIS.—Prominence of respiratory or bowel symptoms in typhoid fever may cause the infection to be overlooked. A deep-seated or apical pneumonia or, in children, broncho-pneumonia with intestinal disturbance, may simulate typhoid. Careful and repeated physical examination, blood and stool culture and agglutinative reactions will lead to a correct diagnosis. Labial herpes is rare in typhoid. When typhoid is prevalent, caution is necessary in diagnosing primary bronchitis, pneumonia, broncho-pneumonia and, especially in children, gastro-enteritis.

Differentiation from acute miliary tuberculosis, from tuberculous meningitis and from tuberculous peritonitis is often difficult. Acute miliary tuberculosis may simulate typhoid in its insidious onset with malaise and headache, its rising temperature with morning remissions, its occasional slow pulse, its bronchitis and perhaps some enlargement of the spleen. But the temperature tends to be more irregular, sweats are present, the dyspnoea and cyanosis are suggestive, and signs of pleurisy may develop. There are no rose spots, and agglutinative tests and blood culture give negative results (tubercle bacilli are rarely found). Tuberculous meningitis is differentiated by such symptoms as vomiting, convulsions, the persistence of headache after the first week, or when delirium is established. A pulse hardly raised above the normal rate, stiffness and retraction of the neck, the presence of Kernig's sign and of retraction of the abdomen or the onset of ocular paralysis are very significant. The irritability and curled-up decubitus of meningitis contrasts with the apathy and dorsal decubitus of typhoid. Lumbar puncture will clinch the diagnosis; in tuberculous meningitis lymphocytes are in excess in the cerebrospinal fluid, and sometimes tubercle bacilli may be demonstrated. The question of meningo-typhoid has already been discussed. Tuberculous peritonitis may resemble mild typhoid fever. The presence of tuberculous masses in the abdomen or the development of peritoneal or pleural effusions is significant. In cases with indefinite symptoms and no signs of tubercle elsewhere, negative blood culture and agglutination tests afford assistance in eliminating typhoid infection.

Suppurative and pyæmic conditions may give rise to fever and constitutional disturbance bearing some resemblance to typhoid. Among these must be mentioned appendicitis and the intraperitoneal abscesses which may result from it, perinephric abscess, cholecystitis, pelvic, or puerperal infections, infective endocarditis and deep-seated osteomyelitis. The diagnosis is made by careful attention to the history of onset and course, thorough and complete physical examination, and the frequent presence of a pronounced polynuclear leucocytosis. Profuse sweats and rigors are more likely to occur, and the temperature chart is more irregular. The blood serum fails to agglutinate typhoid bacilli, nor can they be obtained by blood culture, which may, however, reveal the presence of other organisms.

Typhoid fever in its early stages is often mistaken for influenza, but in the latter the onset is generally sudden and the early symptoms are more severe. The temperature reaches its maximum much sooner. The pains in the limbs and the backache are more intense, and the headache, which has a neuralgic character, is frequently supra-orbital. Catarrh of the conjunctiva and nose may be present, and perspirations are often marked. Defervescence usually takes place within a few days. A sharp drop of temperature after 2 or 3 days with a sudden rebound 12 or 24 hours later is very characteristic. If a supposed influenzal fever persists without definite cause, typhoid should be suspected.

A mild infection with typhus may bear a close resemblance to typhoid, and severe typhoid with grave toxæmia, stupor and a profuse eruption may be mistaken for typhus. Points in favour of the disease being typhoid are a slower onset, later appearance of the eruption, which is never petechial and presence of bowel symptoms. Typhus, on the other hand, has a sudden onset with high fever which sooner attains its maximum and does not show morning remissions. Conjunctival injection, con-

tracted pupils and a drunken expression are the rule. The rash appears on the fourth day, becomes petechial and is accompanied by subcuticular mottling. Prostration is marked and there is a greater tendency to early delirium or stupor. Desquescence, more or less abrupt, occurs about the fourteenth day. The Weil-Felix reaction is present, but agglutination tests for typhoid are negative except in inoculated persons (p. 296).

① *Undulant (Malta or Mediterranean) fever* is distinguished from typhoid by its persistently relapsing character, the prominence of arthritic pains and joint swellings, and the fact that the blood agglutinates the *Brucella melitensis*, which organism can also be recovered by blood culture. Closely allied to this is the fever produced by *Br. abortus* of cows and pigs.

② When *malarial fever* assumes the continuous type, which is likely to occur with the malignant infections, the diagnosis turns on known exposure to malaria, sudden onset, the detection of malarial parasites in the blood or bone marrow and the reaction to anti-malarial drugs. Malaria and typhoid fever, however, may coexist.

③ The fever of *secondary syphilis* is sometimes sufficiently severe to suggest typhoid, especially when accompanied by headache, malaise and muscular pains. In the *tertiary stage with gummata* of the liver prolonged fever may also occur. Diagnosis depends on the history or detection of a primary lesion, the possible presence of a secondary roseolar eruption and on laboratory tests. *Deep-seated malignant disease*—or *hypernephroma* may also cause prolonged fever.

Amongst other diseases at times confounded with typhoid must be mentioned amebiasis, psittacosis, kala-azar, glanders, trichiniasis, fever due to *Ascaris lumbricoides*, scarlet fever in which pyrexia is prolonged, that type of glandular fever in which the glandular swelling is delayed, and especially fevers of the Salmonella Group, i.e. paratyphoid A, B or C.

Prognosis.—Taking all ages, the death-rate varies from less than 5 to 25 per cent. as it is higher in some epidemics than in others. Age has a decided influence, especially on the mortality, which is least in children from 5 to 10, after which there is a steady increase with advancing years. Infants are believed to stand the infection very badly. Obesity, alcoholism, privation and fatigue are adverse factors. The influence of pregnancy has already been discussed. Indications of a grave attack are a pulse-rate of 130 or 140, cyanosis with signs of failing circulation and hypostatic congestion of the lungs, marked delirium and subsultus or actual coma, oliguria, persistent diarrhoea, tympanites, incontinence of urine and faeces. A temperature of 103° or 104° F. is not necessarily unfavourable unless it is sustained beyond the usual period or accompanied by signs of heart failure. Delayed appearance of the agglutnative reaction in some instances indicates a severe attack.

Of the complications, next to toxæmic circulatory failure, perforation is the most grave. Without operation it is almost invariably fatal. With operation the recovery rate is difficult to fix—some surgeons claim success in over 30 per cent., but the intervention must be immediate. The average recovery rate is very much lower. Haemorrhage from the bowel is undoubtedly serious, especially if repeated. Such complications as meteorism, meningitis, lobar pneumonia and acute nephritis are dangerous but not very common.

Sudden death sometimes occurs, either at the height of the fever or in convalescence. It may be caused by intense toxæmia and circulatory failure, coronary or pulmonary thrombosis or pulmonary embolism. Rarely no definite cause can be assigned.

Treatment.—**PROPHYLACTIC.**—Patients should be isolated. Adequate disinfection of the faeces, the urine, the pus from abscesses, the vomit and the sputa is necessary. Blood discharged from the nose or bowel should also be looked upon as infectious. Equally essential is the disinfection of the bedclothes and personal linen of the patient, the feeding utensils, thermometer, bed-pan, urinal, spittoon and enema

syringe The stools and urine should be mixed with an excess of some such disinfectant as carbolic acid, and allowed to stand for several hours before being thrown down a drain The sputa should be received in small cloths which can be burned or expectorated into a disinfectant solution The clothing and bedclothes of the patient should be kept wet and soaked in a 1 in 20 solution of carbolic acid before being sent to a laundry

Nurses in attendance should submit to prophylactic inoculation and take special precautions for their own safety Overalls will obviate soiling of the clothes Rubber gloves may be worn when giving enemas touching bed pans and urinals or dealing with soiled linen, but always it should be realised that typhoid acquired by contact is a disease conveyed by unclean hands, and the danger may be obviated by washing with plenty of soap and water after touching the patient or anything which has been in contact with him Everything leaving the patient or used by him must be sterilised at once Feeding utensils should be boiled after use

In most cases the bacilli disappear from the excreta in convalescence, only persisting for a few weeks but bacteriological examination several times repeated affords the only proof of safety This may be supplemented by an examination of the blood for the Vi agglutinin About 5 per cent of those attacked become carriers In most the carrier state is temporary and an arbitrary period of 6 or 12 months is allowed before the condition is deemed chronic Intestinal carriers are more common than urinary carriers In both the discharge of bacilli may be intermittent Symptoms referable to the gall bladder and periodic bowel disturbance occur in some intestinal carriers and urinary carriers in like manner may suffer from kidney trouble or cystitis Female carriers are said to be more common than male Carriers do not necessarily give a positive Widal reaction but Felix states that use of the Vi antigen will detect them (see p 105)

Carriers are often responsible for the endemic persistence of typhoid in certain communities or localities and are particularly dangerous when employed in the preparation of food or in dairy work or in connection with water supplies They should be prohibited from following these occupations Since they may spread infection by contaminating their own hands during defæcation or micturition they should be scrupulous in washing after attending to the calls of nature and have towels reserved for their own use Their soiled bed and body linen must be disinfected Medical treatment by the use of intestinal and urinary antiseptics, surgical by excision of the gall bladder, and treatment by autogenous vaccines have up to now alike failed to solve the problem of the chronic carrier It is said that sulphaguanidine is sometimes effective Preventive inoculation of contacts is the most effectual method of limiting their danger and is adopted in special circumstances Some carriers give no history of an attack of typhoid and may themselves ultimately develop an attack of the fever or suffer from typhoid septicæmia after operations on the gall bladder

virulent to mice. This stimulates formation of V_1 and O agglutinins and has proved highly effective. The vaccine commonly used contains 1000 million *S. typhi* and 750 millions each of *S. paratyphi A* and *B* per ml. The standard dose is 0.5 ml, followed by 1 ml after an interval of 10 to 14 days. Smaller doses of alcohol-killed vaccine are required, for men 0.3 ml and 0.6 ml. Thereafter an annual dose is desirable to maintain immunity.

Vaccine injection is made subcutaneously and preferably not after a heavy meal or exposure to fatigue. A mild local reaction and sometimes constitutional symptoms may occur a few hours after injection, hence the patient should rest. If the patient is already infected the reaction may be more severe. The duration of the immunity conferred is said to average 1 to 2 years and to be proportional to the dosage employed. An individual inoculated at the beginning of the incubation period of typhoid has a good chance of escaping the fever, but in rare cases the inoculation appears to precipitate its onset and aggravate its course (*provocation typhoid*).

CURATIVE—The sulphonamides exert little or no influence upon typhoid fever and, of the antibiotics, chloramphenicol alone has been shown to be truly effective. Administration of this drug by mouth is followed by defervescence of the fever in 3 or 4 days and by disappearance of the toxæmia. However, relapse has been noted after its use, and the dangers of hæmorrhage and perforation are not completely abolished. The dosage originally recommended was 4 g followed by 0.25 g 2-hourly for 5 days. Only recently has the occasionally devastating effect of chloramphenicol on the bone-marrow been recognised, and it is not yet known how frequently its use is followed by aplastic anæmia. At present it seems justifiable to continue its employment in typhoid fever, although wise to administer it only for a period of 5 days. It should, perhaps, be mentioned that the foregoing account of typhoid fever is of the disease unmodified by the use of chloramphenicol.

Skilful nursing and suitable diet are of the first importance. The room should be kept at a temperature of $60^{\circ} F$, the bed narrow and of convenient height. A hur or rubber mattress is covered with two folds of blanket and a waterproof sheet over which is placed a sheet, and under the hips a draw sheet. A water-bed is unnecessary. A sheet and coverlet with a blanket over the feet are usually sufficient covering. Night and morning the patient should be sponged with tepid water, and parts exposed to pressure should be rubbed with surgical spirit, and dusting-powder applied. Rucking of bedclothes should be avoided. The urinal and bed-pan should be used in the recumbent position, and the buttocks sponged, dried and powdered after each motion. The mouth should be cleansed after each meal. From time to time it may be advisable to move the patient from the dorsal position to avoid hypostatic congestion of the lung bases. Stools and urine should always be reserved for inspection by the medical attendant, who should never neglect daily examination of the abdomen, and should also satisfy himself that the patient, especially if restless, has not retention of urine. Examination of the veins of the legs should never be omitted. The temperature, pulse and respirations should be charted 4-hourly, and more frequently should complications be suspected.

The principles of the dietetic treatment of typhoid fever are to provide an adequate allowance of fluid, calories and vitamins while avoiding foodstuffs which leave a bulky residue. The requirements of fluid vary, but may reach 5 to 6 litres a day with high fever. An adult will require 3000 calories daily which may be derived from eggs, steamed white fish, minced meat, milk, cream, ice-cream, purée of potatoes and thickened soups and should be given as frequent small feeds. Fluid and calories may be provided in the form of strained fruit juices, sweetened with glucose or lactose. A supplement of vitamins is essential.

When the temperature has been normal for 3 days more bulk is cautiously added to the diet.

Tepid, cold or ice sponging should be adopted when the temperature is high, or

the cold pack used, especially when nervous symptoms are pronounced. The ice cradle is another useful means of refrigeration; the patient is covered with a sheet, and a cradle, in which small rubber bags of ice are suspended, is placed over the body, the whole being covered with a thin blanket. The cradle may remain in position indefinitely, the effect on the temperature being carefully watched.

Constipation should be met by a simple enema every second day. In defervescence liquid paraffin may be substituted. *Diarrhoea*, if accompanied by curds, calls for reduction of the milk. A starch and opium enema is useful, or gr. 10 of Dover's powder by the mouth. In *haemorrhage from the bowel* the most absolute rest is essential. Food should be reduced to a minimum or withheld for 12 or 24 hours. No stimulants or beef-tea are permissible. Ten minims of laudanum or a hypodermic injection of gr. $\frac{1}{4}$ of morphine should be given. A watch should be kept for signs of perforation. Blood transfusion will be necessary if the haemorrhage is voluminous. *Perforation of the bowel* calls for immediate operation. *Meteorism* may be controlled by reducing the diet, administering copious enemata of hot water and inserting the rectal tube. A turpentine stupe or ice-poultice may be applied to the abdomen. Turpentine by the mouth or by enema (half an ounce in 8 oz. of mucilage of starch) is useful. For *delirium*, *sleeplessness* and *headache*, the reduction of temperature by sponging or cradling and the administration of gr. 10 or 15 of Dover's powder should be tried. Sometimes soluble barbitone (Medinal) and aspirin are effectual. In *circulatory failure* nikethamide, leptazol and digitalis are of very doubtful value. The supervention of *femoral thrombosis* calls for strict immobility of the limb. Evidence of the value of anticoagulants in typhoid is not yet forthcoming, but these drugs are to be avoided until all risk of haemorrhage is past. *Bacilluria* and *cystitis* are treated by hexamine in gr. 10 doses, three or four times a day; if persistent, sulphonamides may be effective. Of the suppurative and septic complications, *periostitis* may be influenced by rest, local applications and typhoid vaccine, but suppuration calls for surgical intervention. *Parotitis* usually comes to incision. *Cholecystitis* may subside, and should be given a chance to do so, but if it persists operation becomes necessary. Crops of boils call for local treatment, and penicillin or sulphonamides.

CONVALESCENT.—In an infection of moderate severity the patient should be able to be up for a short time 10 days after the temperature has become normal. Few are fit to work until 2 or 3 months have elapsed.

Three negative stool cultures at intervals of 7 days should be obtained before discharge. The Vi agglutination should be tested. If it remains positive the carrier state is suspected and it should be repeated in 3 months.

monly a chronic carrier. The contagion may be direct or through food, drinking water or fomites. Foods not safeguarded by cooking after purchase are common vehicles of infection. Amongst these are bread; cream, synthetic or natural, ice-cream, cream pastries, cooked beef, ham and some shell-fish. Extensive water-borne outbreaks are rare, but the organisms may flourish in sewage or sewage-effluents for 3 weeks. Milk infection is usually through the agency of infected water or of a carrier. The incubation period varies from 10 to 12 days. Extremes of 4 to 24 days are known. Precocious carriers have been known to harbour the bacilli for as long as a month before developing the disease.

Symptoms.—The clinical manifestations of paratyphoid are similar to those of typhoid fever, but are generally of a milder character with a speedier ingravescence and a shorter course. Ambulatory, or almost symptomless, attacks are common, and during outbreaks the number of transitory carriers is much in excess of the cases of overt infection. On occasions, however, paratyphoid may show a severity equal to that of true typhoid. Simulation of attacks of acute irritant food-poisoning is also alleged, but these are more likely to be due to *Salm typhi-murium* or to mixed infections. The septicæmic stage of paratyphoid is short, rarely lasting more than a week and blood cultures for diagnostic purposes should be taken as early as possible. They are said to prove positive in 90 per cent. of the cases.

The onset is usually insidious, the invasive symptoms resembling those of typhoid, but a sudden onset is believed to be more common than in the latter disease. Shivering and vomiting are not infrequent symptoms of such invasion. Sometimes gastrointestinal symptoms are for a time very prominent, and are particularly misleading in childhood. As with typhoid, bronchitis, influenza or pneumonia may at first be simulated, and sometimes the symptoms simulate an acute abdominal condition or meningitis.

The fever attains its maximum sooner than in typhoid, and may be at its height by the third or fourth day, by which time, if not before, the patient will have taken to bed. The head aches, also the back and limbs and sometimes the joints. The patient is apathetic, and the spleen usually becomes palpable, it is firm and sometimes tender. The liver may be slightly enlarged, and the gall-bladder tender if cholecystitis is present. The abdomen is generally somewhat tumid, but marked distension is uncommon. Diarrhoea may occur at the onset, but constipation is more common. Sweating is often more pronounced than in typhoid. Rose spots are present in unusual profusion in some cases. They usually appear towards the end of the first week. Their distribution resembles that seen in typhoid fever. They often appear larger than those seen in ordinary typhoid infection, and the rash may continue to come out after the temperature has fallen. Pulmonary complications are mild, but bronchitis and broncho pneumonia may occur. In the more severe cases, circulatory failure may be evident.

After the first week the toxæmia rapidly diminishes and it is exceptional for the patient to pass into the "typhoid state". The fever has a shorter duration and is more often remittent than in typhoid. Within a fortnight, sometimes sooner, it has generally fallen by rapid lysis to normal. The slow pulse and low blood pressure of typhoid are also seen in the paratyphoid variety, and the blood picture, in minor degree, also resembles that of typhoid fever. Relapse is said to be just as frequent. Convalescence is rapid.

Complications.—In some cases bronchitis, or broncho pneumonia, are prominent and may mask the real nature of the infection. Intestinal hæmorrhage is much less common and less severe than in true typhoid. Perforation is rare. Thrombosis of the femoral or saphenous veins or their radicles is not uncommon, and pleural effusions may occur. Cholecystitis may be due to paratyphoid organisms, as also bacilluria, cystitis, pyelitis and even pyelonephritis. Orchitis is an occasional complication. Other complications, which have mostly been observed in army practice,

are laryngeal ulceration, parotitis, **periostitis**, **peritonitis**, sometimes without perforation of the bowel, and **pylephlebitis**, attributed to lesions of the appendix.

Diagnosis—For the differentiation of paratyphoid from typhoid and of the varieties of paratyphoid from each other, recourse must be had to bacteriological methods, i.e. to blood culture, agglutinative reactions and cultures from the stools and from the urine. Of these methods, **blood culture** in the early stages is the most satisfactory. In the inoculated, if agglutination occurs in high dilutions with one of the paratyphoid organisms and little or not at all with the others and with the organism of typhoid, the nature of the infection is evident, but in other cases the examination has to be repeated at short intervals and the results compared. A rising agglutination for one organism indicates it as the causal agent. The possibility of confusion with *Salm typhi-murum* and of anamnestic reactions should be borne in mind.

Prognosis—The prognosis in paratyphoid infections is better than in those due to the *Salm typhi*, the proportion of severe infections being much smaller, and the mortality much lower. The fatality in recent outbreaks has ranged from 1 to 3.5 per cent. The causes of death are chiefly **hæmorrhage**, **perforation**, **lung inflammations** and **toxæmia**.

As regards differential diagnosis, phage typing, prophylaxis and treatment, what has already been said with regard to typhoid applies. Sulphonamides are of very doubtful utility.

R. BODLEY SCOTT

such as the Netherlands East Indies, where the natives defæcate directly into flowing water or streams running into rivers, the disease is predominantly water borne and prevention consists essentially in water sterilisation. In the Middle East, however, infection is mainly fly borne. Uncooked vegetables, particularly salads, should be suspect, as human excrement is so often employed as manure. Cooks and food-handlers who are carriers are also a potent source of infection. Recent technical advances in culturing dysentery bacilli have shown that a larger proportion of dysentery patients become carriers than was formerly thought.

Shiga (1898), in Japan, first discovered *Sh. shiga*, which is a most virulent organism producing a true exotoxin. This was rapidly followed by the isolation of several other strains of dysentery bacilli. Boyd, who has recently reclassified the organisms, causing bacillary dysentery, recognises two non-mannitol fermenting bacilli, *Sh. shiga* and *Sh. schmitzi*. Of the mannitol fermenting dysentery bacilli there is *B. dysenteriae* Sonne, which is a late lactose fermentor, and two groups of non-lactose fermenting organisms which include six types of *Sh. flexneri*, i.e., I, II, III, IV, V and VI, and three types of *Sh. boyd*, i.e., I, II and III. The latter types have been found in India, the Middle East and New Guinea, and probably have a still wider geographical distribution. More than half the dysentery in warm climates is caused by organisms of the Flexner-Boyd group. In the Middle East, *E. histolytica* accounted for 12.3 per cent, *Sh. shiga* for 15.8 per cent, and Flexner-Boyd I for 52.3 per cent of Army cases in 1941.

Pathology—While the naked eye pathology of fatal cases is well known, the macroscopic appearances of the bowel in non-fatal cases can only be investigated during sigmoidoscopic examinations of the rectum and pelvic colon. Combined studies have shown a wide range of pathological lesions, including (1) transient catarrhal inflammation with hyperæmia associated with increased mucoid secretion but without ulceration, (2) more severe generalised inflammation with hyperæmia, œdema, scattered hæmorrhages and localised areas of coagulation necrosis of the mucosa, exfoliation of which subsequently leads to superficial ulcers covered with mucopus, and (3) widespread coagulation necrosis of the mucosa, which, in fulminating cases, is characterised by a greyish-white or greenish gangrenous membrane. Cases dying in the acute phase of the disease often show extensive ulceration, which may involve the whole colonic mucosa, and sometimes the terminal 12 in. of the ileum as well, in others maximal lesions are found in the rectum, sigmoid colon and cæcum. Fatal cases have also shown hæmorrhagic inflammation and swelling of the meso-colonic lymph glands, parenchymatous degeneration of the liver and kidneys and central necrosis of the suprarenal glands. The pathological findings in subacute and chronic bacillary dysentery are considered later.

Symptoms—The incubation period is from 1 to 7 days. The clinical features vary with the resistance and age of the patient, and the type of the invading organism. Thus, Flexner-Boyd and Sonne infections are generally mild and Shiga infections frequently severe. In infants, however, Flexner infections may be rapidly fatal, greenish fluid stools containing typical bacillary exudate being passed.

Acute, subacute and chronic clinical types of dysentery may be encountered

ACUTE DYSENTERY

The Flexner-Boyd Group—Many cases are of mild catarrhal type, and, as a rule symptoms of severe toxæmia and dehydration do not develop.

The onset is characterised by colicky abdominal pain, followed by urgent diarrhoea. Nausea, transient vomiting, headache, shivery feelings and aching in the limbs may accompany, follow or precede the onset of abdominal symptoms. Fever is present soon after the onset of diarrhoea in most cases. Examination reveals diffuse tenderness, most marked over the right or left iliac fossa, or the upper part of the abdomen.

The abdominal pain is predominantly *colicky* in character. Between the paroxysms the patient may get relief or complain of a persistent dull ache. Tenesmus due to rectal spasm is less frequent in mild than in severe infections.

Diarrhoea is generally most intense on the first and second day of attack, the stools, as a rule, decreasing in number thereafter, but in some cases the maximum number is reached on the third, fourth or fifth day. At first the stools are fairly copious and watery, but, if looked for, flakes of mucous and blood will generally be found. Most cases of febrile diarrhoea in which numerous liquid stools are passed are bacillary dysentery. As the condition develops, the stools are found to consist almost entirely of mucus or of blood and mucus. The mucus is like egg white, practically odourless, tenacious and sticks to the bed-pan. The blood varies in quantity, and may be seen as mere flecks in otherwise colourless mucus or may be more copious. In more severe cases the mucus becomes yellow and definitely purulent in character. As the case advances towards recovery blood disappears, mucus becomes more scanty and thicker, and brown faecal matter reappears. In mild cases fever and diarrhoea may last only 1 or 2 days, while in others it goes on for a week or more. If sulphonamide treatment is being given and the pyrexia or diarrhoea persists more than a week, sigmoidoscopic examination should be made.

Shiga Type—(1) Fulminating cases of Shiga dysentery are occasionally encountered. The onset is sudden, with vomiting and severe watery diarrhoea. The patient rapidly becomes collapsed and dehydrated, muscular cramps ensue and death with subnormal temperature may supervene in 24 to 36 hours. In these cases the terminal portion of the ileum is frequently involved. As mucus secretion from the necrosed colonic mucosa is impossible, the typical mucosanguineous stools of dysentery may never appear. The copious fluid stools may suggest cholera or food poisoning, and the correct diagnosis may only be made at necropsy.

tonitis with serous effusion results. Under these circumstances the abdomen becomes distended, the abdominal muscles tender and somewhat rigid and there may be dullness in the flanks or free fluid demonstrable. Flatulence, vomiting and colicky abdominal pain prove troublesome. A polymorphonuclear leucocytosis is characteristic. The condition is non-surgical, and must be differentiated from acute peritonitis secondary to perforation which demands immediate laparotomy.

(3) The less severe Shiga infections present much the same picture as the Flexner-Boyd group already described. They cannot be differentiated clinically and can be diagnosed only by bacteriological methods.

Sonne Type—This type particularly affects children, but may also occur in epidemic form in adults. The clinical picture is frequently mild, resembling that described in the Flexner-Boyd group.

Since the introduction of sulphonamide therapy, subacute and chronic dysentery are rare and only encountered in untreated or inadequately treated patients.

SUBACUTE DYSENTERY

In the subacute stages of dysentery, looseness of the bowels and the passage of stools showing mucus and traces of blood persist. Fever may or may not be present.

Sigmoidoscopy generally reveals ulcerative lesions which are not necessarily associated with generalised inflammation of the mucosa. The ulcers seen may be (1) small, superficial and clear cut with well-defined edges, (2) like aphthae with yellowish-white exudate, (3) punched out in appearance, with vertical walls and covered with mucus, or (4) small discrete nodular like lesions with a yellow crust, on scraping a bleeding crater is left containing exudate of bacillary type from which dysentery bacilli can be cultured. Patients with these small local ulcers and normal intervening mucosa may have periods of complete remission of symptoms, interspersed with mild attacks of looseness of the bowel, and the passage of stools containing mucus and possibly blood.

CHRONIC DYSENTERY

Rogers found that chronic bacillary dysentery mainly involved the rectum, sigmoid and ascending colon. Two types are encountered.

(1) The patient gives a history of dysentery from which he has failed to recover. Looseness of the bowels ensues, the stools containing mucus, mucus and sometimes blood. In some cases the bowels may have acted 5 or 6 times every day for 6 months or longer. Sigmoidoscopy reveals normal mucous membrane interspersed with circular or oval ulcers up to 1 cm. in diameter. Microscopic examination of the mucus obtained during this examination shows bacillary exudate, and culture is positive for bacilli, especially of Shiga variety.

(2) The patient gives a similar history, but is more ill, and during exacerbations fever may recur. Evidence of malnutrition is more marked, the loss of weight is greater and such patients tend to become miserable and emaciated. Secondary anaemia and oedema of the legs may develop. The abdomen is scaphoid, and the thickened descending colon is readily palpable during physical examination. Sigmoidoscopy reveals that the large bowel is tubular in outline, thickened and contracted and difficult to distend. The surface is composed of red granulation tissue, which bleeds readily on instrumentation. The general appearance resembles that seen in ulcerative colitis, and in severe cases the patulous condition of the anus, the atrophied appearance of the perianal skin, and the wasting of the gluteal and perineal muscles are common to both diseases. The radiological picture also shows a smooth tubular bowel with loss of haustration. In chronic dysentery of this type the inflammatory process extends deeply, involving the muscular coats leading to thickening, fibrosis

and loss of function. Culture of muco-pus obtained at sigmoidoscopy may reveal dysentery bacilli, and so differentiate the condition from ulcerative colitis.

Complications and Sequelæ.—Complications in both Flexner-Boyd and Shiga types of dysentery are infrequent, and are mainly encountered in the severe infections. Intestinal complications include hæmorrhage, which may be severe, especially in Shiga infection, perforation with peritonitis, chronic peritonitis with localised or general effusion of peritoneal fluid, hæmorrhoids, rectal prolapse and painful excoiation of the anus. Peripheral circulatory failure and renal failure are not uncommon complications in severe Shiga infections, and have been already described. Peripheral neuritis, toxic arthritis, conjunctivitis, iritis, pneumonia, parotitis, petechial and purpuric skin rashes occasionally occur. Toxic arthritis is found in both Flexner and Shiga dysentery. It takes the form of effusion into joints and peri-arthritis, and generally comes on from the third to fifth week, or during convalescence. The large joints are prone to be attacked. It often persists for many weeks, but recovery without permanent deformity follows.

Diagnosis.—Many cases regarded as simple diarrhœa are caused by dysentery bacilli. In bacillary dysentery the attack is almost invariably heralded by colicky abdominal pain, followed by urgent diarrhœa. Fever is generally present at the first examination, which may reveal localised abdominal tenderness in the course of the colon. The stools may be liquid in consistency and brown in colour at onset, but even at this early stage careful examination will generally reveal flakes of mucus containing exudate of bacillary type. In a typical case the stools show clear glassy mucus, with or without bright-red blood, and later muco-pus. Any case suddenly developing colicky abdominal pain, urgent diarrhœa with flakes of mucus or naked-eye mucus with or without blood in the stools and fever should be regarded as bacillary dysentery, until proved otherwise. When feasible this tentative diagnosis should be confirmed by laboratory investigation and, if necessary, by sigmoidoscopy. Typical bacillary exudate is composed predominantly of polymorphonuclear leucocytes, with or without macrophages, epithelial cells and red blood corpuscles. Stools sent for culture should contain mucoid exudate, be absolutely fresh and uncontaminated by urine or antiseptics, they carry well in a solution of 30 per cent glycerin in physiological saline. Dysentery bacilli may be isolated at any stage of the disease, especially if material for culture be obtained during sigmoidoscopy or by rectal swab. Using modern media positive cultures may also be obtained from stools containing no macroscopic mucus.

misdiagnosed as subacute or chronic bacillary dysentery. Sigmoidoscopy and radiograms after a barium enema may be essential in their differential diagnosis.

Course and Prognosis—Most non-Shiga dysentery infections run a benign course, and many cases of catarrhal type are so mild that they clear up in a few days without specific treatment, in others, fever and intestinal symptoms persist for 1 to 3 weeks before subsiding, and in a minority, subacute or chronic dysentery may result. Fatal cases are generally of Shiga type, death occurring in from 30 hours to 3 months of onset. In some epidemics, especially amongst Japanese and debilitated natives, the mortality rate has been 25 to 50 per cent. In infants and young children, the aged and people who are malnourished or suffer from intercurrent disease, bacilli of Flexner, Schmitz and Sonne types may cause death. The mortality rate in British Forces in Egypt, Macedonia and Mesopotamia during the War of 1914-1918 was 27 per 1000. In Australian troops in New Guinea in the War of 1939-1945 it did not exceed 0.5 per 1000, a result attributable to the lower incidence of Shiga infections and the efficacy of early sulphaguanidine therapy. (See also Specific Chemotherapy, below.)

Treatment—**PROPHYLACTIC**—As dysentery is spread by water or food contaminated either directly from a patient or human carrier or indirectly by flies, measures similar to those adopted for enteric fever and cholera are indicated. No satisfactory prophylactic vaccine is available. Sulphonamides, by limiting the number of stools and rendering them non-infective, constitute a potent means of controlling epidemics, and by curing the patient they prevent the development of carriers.

CURATIVE—Rest in bed and good nursing are essential. Special attention should be directed to the correct dosage of the particular sulphonamide administered, maintenance of a positive fluid balance to prevent dehydration, regular feeding, the hygiene of the mouth and the prevention of bed sores.

Dietary—In all cases for the first 24 hours only water is allowed to which may be added glucose, lactose or cane sugar. Subsequently, albumen or barley water, tea and chicken broth are given, followed by soups, Marmite, orange juice, jelly, biscuits, dry toast, clear honey, whey, Sprulac and apple puree. Later, arrowroot, cornflour, ground rice, sago puddings and, as improvement continues, by eggs, non-fatty fish, chicken, butter, milk drinks, junket and stewed fruit may be taken. Adherence to this type of low residue diet is only necessary in severe cases, especially Shiga infections, in order to rest the bowel, in dysentery of ordinary severity and of non-Shiga type, milk drinks, milk puddings, toast and cereals may be introduced as first additions to the initial diet of clear fluids and jellies once the stools have been reduced to 6 to 10 per day, and proteins are allowed shortly afterwards.

Specific Chemotherapy—Various sulphonamides, including sulphaguanidine, succinylsulphathiazole and sulphadiazine, have been shown to exert specific curative effects in bacillary dysentery. Owing to its poorer absorption, lower toxicity and absence of renal complications, sulphaguanidine (p-*amino* N-guanylbenzene sulphonamide) has special advantages over most of the other sulphonamides for use in hot climates in dehydrating intestinal diseases like Shiga dysentery and cholera which may be complicated by renal failure and anuria. Crystals of acetyl sulphaguanidine do appear in the urine, but they are deposited as a soft mush and not in the form of hard renal concretions, as in the case of most other sulphonamides. Once a tentative diagnosis has been made on clinical grounds, specimens of the stool should be obtained and forwarded to the laboratory for a report on the microscopic and cultural findings. Treatment, however, should not be delayed pending the laboratory report for by so doing valuable time is lost.

Sulphaguanidine in acute dysentery is given in a dose of 0.05 g. per kg. 4-hourly for the period during which the number of stools passed exceeds 5 per day, and subsequently a dose of 0.05 g. per kg. every 8 hours until the stools have been normal in number and consistency for 2 days. The duration of treatment should not exceed

12 days, but if necessary the course can be repeated after the lapse of a week. Thus, a patient weighing 11 stooe would receive 3.5 g. 4-hourly, and later the same dosage 8-hourly. An initial dose of 0.10 g. per kg. body weight is often given. With Shiga dysentery, if the patient is not treated until the third day or later, it is not uncommon for 150 to 200 g. to be administered over a period of 8 to 12 days.

The response of acute dysentery to sulphaguanidine therapy is remarkable. If the drug be given within a few hours of onset, the attack of dysentery is generally aborted; fever disappears, the diarrhoea and abdominal pain cease in 24 hours and the stools soon become normal. In Shiga cases when treatment is delayed 2 or 3 days or longer, inflammation and destruction of mucous membrane have already resulted. Despite this, the response is generally striking. There is an early feeling of well-being, rapid relief of abdominal pain and a decrease of abdominal symptoms. In uncomplicated cases an early reduction of the temperature and pulse is noted, the normal being reached in most cases in 1 to 3 days. There is also a remarkable reduction in the number of stools, and blood disappears rapidly from the faeces and mucus a few days later. When the treatment of Shiga dysentery commences from the third day to the third week of the disease, normal bowel action can be expected in about 5 to 6 days, and formed stools in about 8 days.

In subacute and chronic cases, in which the bowels are acting some 3 to 8 times daily, the treatment consists of 0.05 to 0.1 g. per kg. every 8 hours for 7 to 10 days. Should this not be effective it will be necessary to repeat the course later or to substitute one of the other sulphonamides for sulphaguanidine.

Full dosage and a complete course of treatment as prescribed for chronic dysentery is the most effective means of eliminating the carrier state.

If colicky pain or tenesmus are severe during the first 24 hours, morphine gr. $\frac{1}{4}$ may be given and repeated next day, but this is rarely necessary. Heat in the form of antiphlogistine or turpentine stupes applied to the abdomen may also be helpful before sulphaguanidine has exerted its maximal beneficial effects. Dehydration should be prevented by administering as much fluid per os as can be comfortably taken. The fluid intake should be sufficient to ensure the secretion of 2 pints of urine daily. When there is severe vomiting or copious fluid stools, intravenous injections of saline (0.85 per cent.) or glucose (5.0 per cent.) solution are administered either intermittently or by continuous drip. Blood transfusion is advisable if the patient is markedly

200,000 I U may be repeated every 4 to 6 hours. This anti serum possesses the advantages of rarely, if ever, causing serum sickness or other adverse reactions. Its disadvantage lies in the fact that it is purely anti-toxic and possesses no bacteriostatic or bacteriolytic action on *Sh. shigæ*, for this reason its beneficial effects are only temporary. Polyvalent and multivalent anti-dysenteric sera frequently give rise to serum reactions, and are of very doubtful therapeutic value. No satisfactory anti-sera have yet been produced for the Flexner-Boyd group. Bacteriophage therapy has also proved disappointing. Boyd has recently demonstrated that strains of dysentery bacilli may persist along with their specific bacteriophages in the stools of uncured dysentery patients.

Sodium or Magnesium Sulphate—This was the standard treatment for dysentery before the introduction of specific sulphur drugs. It is now only used if these specific drugs are not available. The initial dose is 2 drachms, subsequently 1 drachm is given 2-hourly for the first 12 to 24 hours, and then 4-hourly, 6-hourly and finally 8 hourly for the next 3 or 4 days or until the stools become faeculent. It is inadvisable to continue sulphate therapy longer than 4 or 5 days, as in many cases it merely keeps up the diarrhoea.

Treatment of complications—Intestinal hæmorrhage is best treated by sulphaguanidine, morphine injections and blood transfusions. Surgical intervention is rarely justified. Perforation of the bowel calls for immediate laparotomy; the prognosis is very grave for the bowel wall is generally necrosed. Joint complications do not generally respond to specific therapy and require treatment along general lines.

N HAMILTON FAIRLEY

FOOD POISONING

The original use of the term food poisoning was based on a misconception. An alternative was "ptomaine poisoning", the belief being that the symptoms were due to toxic products of protein breakdown formed in the course of bacterial decomposition. It is true that highly toxic substances can be formed in this way, but decomposition is by then so far advanced that the smell and taste of the food would be repulsive. What may have been a minor form of this was common during the War of 1939-1945 following the consumption of "torpedoed meat". This came from ships reaching port with damage to their refrigeration plant, at a time when meat was scarce inspectors were reluctant to condemn cargoes in doubtful condition, and such meat, particularly if made into pies, was the cause of severe febrile diarrhoea lasting only a few hours. Whether products of decomposition or perhaps the endotoxins of the various non specific bacteria concerned were responsible for this effect is not certainly known.

On the other hand, most food poisoning is due to the action of specific bacteria or their toxins, and has nothing to do with decomposition. Staphylococcal food poisoning and botulism are produced by pre-formed bacterial exotoxins, and are not infections in the ordinary sense. *Salmonella enteritis*, the commonest form, is simply an infection of the bowel by specific micro-organisms which the food happens to convey. This is really no more food poisoning than are enteric fever or dysentery, which can be conveyed in similar ways.

ACUTE INFECTIVE ENTERITIS (*SALMONELLA*)

Ætiology.—The *Salmonella* group of organisms (named after a bacteriologist the popular supposition that tinned salmon is apt to contain them is quite erroneous) is almost indistinguishable in general characters and fermentation reactions from the group of paratyphoid bacilli. They can be identified only by agglutination tests, and since each may possess from 1 to 3 O antigens and as many as 6 H antigens,

including those characteristic of its two phases, specific and non-specific, an elaborate investigation is often required. Many of these antigens are common to a large number of species, between which the differences, even in antigenic composition, are small, while in all other ways they are indistinguishable. It is thus perhaps unfortunate that over two hundred of these organisms have been accorded the rank of species and given names, often those of places in which they were first isolated. Other bacteria, notably the hæmolytic streptococcus and the pneumococcus, are divisible into many "types" by the same method, but these are merely denoted by numbers.

Much the commonest of these organisms is *Salm. typhi murium*, formerly known as *B. aertrycke*, and next in frequency of occurrence is *Salm. enteritidis* (Gaertner's bacillus). *Salm. sonnei*, *Salm. cholerae* Sait.

Sources of Infection.—The source of infection, as in enteric fever, may be a human case or carrier and, if so, the vehicle may be any uncooked food liable to contamination with human intestinal bacteria (milk, ice-cream, confectionery, salads, shell-fish, etc.). But whereas this is always the ultimate source of either enteric fever or dysentery, diseases which occur naturally only in man, the food-poisoning *Salmonellas* are pathogens of various animals, among which the infections they cause are common and widespread: human infections have therefore usually an animal source.

The animals concerned fall into three classes. Cattle, including both oxen and pigs, are susceptible, suffering from an enteritis which, if severe, may be accompanied by septicæmia. "Emergency slaughter" of animals so affected leads to the marketing of meat containing the bacilli owing to their presence in the blood, the numbers of which can increase greatly by post-mortem multiplication. A temperature of only about 55° C. for half an hour is required to kill them, but this is often not reached throughout in cooking sausages and other pork products or in joints of beef: hence the living bacilli are in the meat as consumed. Another possible method of transmission from cattle is by the milk of an infected cow.

Rodents are also susceptible: indeed, commercial "Rat Viruses" are cultures of a *Salmonella*, sometimes said to be non-pathogenic to man and domestic animals, although this claim is disputable. The contamination of food by rat and mouse droppings is thus a possible source. Finally, poultry and eggs may be concerned. Various *Salmonella* infections are common in hens, and several, previously unknown in Great Britain, were conveyed here from America in dried egg imported during the War of 1939-1945. This product was dangerous only if made up with water and left long enough to permit extensive bacterial multiplication before cooking. Duck eggs are exceptional in that not only the shell but the interior of the egg may contain the bacillus, usually *Salm. typhi murium*. A lightly cooked (e.g. poached) duck egg is often found to have been the cause of an isolated case of this infection.

Pathology.—The characteristic lesion is an acute catarrh of the entire alimentary tract, least marked in the stomach (a point of distinction from chemical irritant poisoning, such as that caused by arsenic) and increasing in degree towards the lower end of the small intestine. The mucosa is swollen and congested, and there may be small submucous hæmorrhages; the lymphoid follicles and Peyer's patches are prominent owing to acute inflammatory changes. The colon is similarly affected and its contents, which are exclusively fluid, include much mucus. Ulceration does not normally occur, but in elderly or debilitated subjects or those suffering from other diseases, the disease pursues a longer course, and ulceration of Peyer's patches, as

Symptoms—Most patients wake with definite symptoms on the day following the consumption of the contaminated food, but the onset may be earlier, or may be delayed for 48 hours or rather longer. The severity of the disease varies considerably, and it is in the mildest attacks with a more indefinite onset that the incubation period may appear to be most prolonged. Malaise, headache, fever and nausea are accompanied by colic, which may be very severe and is soon succeeded by diarrhoea with frequent liquid stools containing much mucus and sometimes unaltered bright green bile pigment, a clear indication that hyperactive peristalsis involves the whole of the intestinal tract. Vomiting is common at the onset but does not persist, and is a much less prominent feature than diarrhoea. Dehydration may be extensive enough to occasion some degree of circulatory collapse, the pulse being of very small volume and the extremities cold and blue. When there is an accompanying bacteraemia, fever is higher and more irregular and rigors may be repeated a rigor at the onset is common. Another unfavourable sign is extreme restlessness. Skin rashes may occur, usually in the form of erythema and urticaria.

Diagnosis—This may be easily made in the presence of an epidemic, but calls for laboratory verification in any isolated or obscure case. The essential investigation is cultivation of the faeces and the identification in them of the causative organism. The results of blood culture may also be of interest in more severely ill patients. An agglutination test performed with the patient's serum is rarely helpful in the early stages, the appearance of agglutinin in the blood being delayed for several days.

It is important to distinguish between this disease and poisoning by arsenic, antimony and other such chemicals, the features of which may be very similar. Examination of vomit, faeces and urine for these substances at once renders this diagnosis clear.

Course and Prognosis—This disease is very rarely fatal in a young and healthy subject. In the old, or those whose resistance is impaired by other disease, it may continue and come to resemble enteric fever not only in its morbid anatomy, as already noted, but in its clinical features, in such patients the mortality has hitherto been considerable. Normally the fever and diarrhoea abate within 3 days, and recovery thereafter is uninterrupted.

Treatment—General measures include rest in bed, and the withholding of food other than water or glucose solution until the more acute symptoms subside. Severe colic at the onset may be an indication for pethidine or, exceptionally, morphine. Dehydration owing to fluid loss may call for intravenous replacement, preferably in the form of glucose saline.

This infection is now also amenable to specific treatment. The sulphonamides of low solubility (e.g. succinylsulphathazole) have some effect, as has streptomycin given by the mouth but the most effective drug is chloramphenicol. Whether this antibiotic, the use of which is not entirely free from risk, should be given to patients in whom the outlook causes no sort of anxiety, is a matter for individual decision, bearing in mind that in the healthy subject this is a self limited disease of very short duration. On the other hand, if bacteraemia exists or is suspected or if the prognosis is unfavourable for any of the reasons already mentioned, chloramphenicol is definitely indicated. 500 mg. should be given, at first at 4-hour and later at 6 hour intervals until fever and other symptoms abate.

The stools should be examined repeatedly during convalescence to determine that the patient is not remaining a carrier.

TOXIC SALMONELLA ENTERITIS

If organisms of the *Salmonella* group have multiplied extensively in food and have subsequently been killed by cooking, the food will nevertheless cause a condition similar to that already described. These organisms possess an endotoxin which is

including those characteristic of its two phases, specific and non specific, an elaborate investigation is often required. Many of these antigens are common to a large number of species, between which the differences, even in antigenic composition, are small, while in all other ways they are indistinguishable. It is thus perhaps unfortunate that over two hundred of these organisms have been accorded the rank of species and given names, often those of places in which they were first isolated. Other bacteria, notably the haemolytic streptococcus and the pneumococcus, are divisible into many "types" by the same method, but these are merely denoted by numbers.

Much the commonest of these organisms is *Salmonella typhi*, formerly known as *B. aertrycke*, and next in frequency of occurrence is *Salmonella enteritidis* (Gaertner's bacillus). *Salmonella*, *Salmonella cholerae* Suis.

Sources of Infection.—The source of infection, as in enteric fever, may be a human case or carrier and, if so, the vehicle may be any uncooked food liable to contamination with human intestinal bacteria (milk, ice cream, confectionery, salads, shell fish, etc.). But whereas this is always the ultimate source of either enteric fever or dysentery, diseases which occur naturally only in man, the food poisoning *Salmonellas* are pathogens of various animals, among which the infections they cause are common and widespread. Human infections have therefore usually an animal source.

The animals concerned fall into three classes. Cattle, including both oxen and pigs, are susceptible, suffering from an enteritis which, if severe, may be accompanied by septicaemia. "Emergency slaughter" of animals so affected leads to the marketing of meat containing the bacilli owing to their presence in the blood, the numbers of which can increase greatly by post mortem multiplication. A temperature of only about 55° C for half an hour is required to kill them, but this is often not reached throughout in cooking sausages and other pork products or in joints of beef, hence the living bacilli are in the meat as consumed. Another possible method of transmission from cattle is by the milk of an infected cow.

Rodents are also susceptible. Indeed, commercial "Rat Viruses" are cultures of a *Salmonella*, sometimes said to be non pathogenic to man and domestic animals although this claim is disputable. The contamination of food by rat and mouse droppings is thus a possible source. Finally, poultry and eggs may be concerned. Various *Salmonella* infections are common in hens, and several, previously unknown in Great Britain, were conveyed here from America in dried egg imported during the War of 1939-1945. This product was dangerous only if made up with water and left long enough to permit extensive bacterial multiplication before cooking. Duck eggs are exceptional in that not only the shell but the interior of the egg may contain the bacillus, usually *Salmonella typhi*. A lightly cooked (e.g. poached) duck egg is often found to have been the cause of an isolated case of this infection.

Pathology.—The characteristic lesion is an acute catarrh of the entire alimentary tract, least marked in the stomach (a point of distinction from chemical irritant poisoning such as that caused by arsenic) and increasing in degree towards the lower end of the small intestine. The mucosa is swollen and congested, and there may be small submucous haemorrhages, the lymphoid follicles and Peyer's patches are prominent owing to acute inflammatory changes. The colon is similarly affected and its contents, which are exclusively fluid, include much mucus. Ulceration does not normally occur, but in elderly or debilitated subjects or those suffering from other diseases, the disease pursues a longer course, and ulceration of Peyer's patches, as in typhoid fever, is commonly found.

Changes elsewhere include the effects of dehydration, some degree of cloudy swelling, particularly in the kidney, and fatty degeneration in the liver. In severe cases accompanied by bacteraemia, the spleen is congested, enlarged and soft. Post mortem investigation should include the preparation of cultures from the heart blood, spleen and intestinal contents—the latter only if a positive culture has not been obtained during life.

Symptoms—Most patients wake with definite symptoms on the day following the consumption of the contaminated food, but the onset may be earlier, or may be delayed for 48 hours or rather longer. The severity of the disease varies considerably, and it is in the mildest attacks with a more indefinite onset that the incubation period may appear to be most prolonged. Malaise, headache, fever and nausea are accompanied by colic, which may be very severe and is soon succeeded by diarrhoea with frequent liquid stools containing much mucus and sometimes unaltered bright green bile pigment, a clear indication that hyperactive peristalsis involves the whole of the intestinal tract. Vomiting is common at the onset but does not persist, and is a much less prominent feature than diarrhoea. Dehydration may be extensive enough to occasion some degree of circulatory collapse, the pulse being of very small volume and the extremities cold and blue. When there is an accompanying bacteraemia, fever is higher and more irregular and rigors may be repeated a rigor at the onset is common. Another unfavourable sign is extreme restlessness. Skin rashes may occur, usually in the form of erythema and urticaria.

Diagnosis.—This may be easily made in the presence of an epidemic, but calls for laboratory verification in any isolated or obscure case. The essential investigation is cultivation of the faeces and the identification in them of the causative organism. The results of blood culture may also be of interest in more severely ill patients. An agglutination test performed with the patient's serum is rarely helpful in the early stages, the appearance of agglutinin in the blood being delayed for several days.

It is important to distinguish between this disease and poisoning by arsenic, antimony and other such chemicals, the features of which may be very similar. Examination of vomit, faeces and urine for these substances at once renders this diagnosis clear.

Course and Prognosis—This disease is very rarely fatal in a young and healthy subject. In the old, or those whose resistance is impaired by other disease, it may continue and come to resemble enteric fever not only in its morbid anatomy, as already noted, but in its clinical features, in such patients the mortality has hitherto been considerable. Normally the fever and diarrhoea abate within 3 days, and recovery thereafter is uninterrupted.

Treatment—General measures include rest in bed, and the withholding of food other than water or glucose solution until the more acute symptoms subside. Severe colic at the onset may be an indication for pethidine or, exceptionally, morphine. Dehydration owing to fluid loss may call for intravenous replacement, preferably in the form of glucose saline.

This infection is now also amenable to specific treatment. The sulphonamides of low solubility (e.g. succinylsulphathiazole) have some effect, as has streptomycin given by the mouth, but the most effective drug is chloramphenicol. Whether this antibiotic, the use of which is not entirely free from risk, should be given to patients in whom the outlook causes no sort of anxiety, is a matter for individual decision, bearing in mind that in the healthy subject this is a self limited disease of very short duration. On the other hand, if bacteraemia exists or is suspected, or if the prognosis is unfavourable for any of the reasons already mentioned, chloramphenicol is definitely indicated. 500 mg. should be given, at first at 4 hour and later at 6 hour intervals until fever and other symptoms abate.

The stools should be examined repeatedly during convalescence to determine that the patient is not remaining a carrier.

TOXIC SALMONELLA ENTERITIS

If organisms of the *Salmonella* group have multiplied extensively in food and have subsequently been killed by cooking, the food will nevertheless cause a condition similar to that already described. These organisms possess an endotoxin which is

heat-stable and is the main cause of the inflammatory reaction in the alimentary mucosa hence if sufficient numbers are present the immediate effect is the same as that following the multiplication of the living organism

This variety of food poisoning is distinguished by a much more rapid and often more sudden onset Colic and diarrhoea begin within 2 to 6 hours of the consumption of the contaminated food This is a useful point of distinction from infection by the living organism, which is not usually apparent until the following day unless very large numbers have been ingested On the other hand, the two conditions may be combined, dead organisms initiating the attack early and a few living ones multiplying to continue it such a mode of infection may account for incubation periods of intermediate length An early onset certainly does not exclude the possibility of living infection, and the stools should always be examined

The typical attack due solely to dead bacteria in the food is not only of more rapid onset but is also, as would be expected from the fact that the cause is not a continuing one, of shorter duration Fever is slight or absent and although dehydration may be dangerous in the elderly, the prognosis is better Diagnosis and the identification of the cause may be difficult or impossible cultures are of course negative and agglutinin formation is slight or absent Cultivation of the suspected food, which, when this is available, should always confirm the source of the living infection, is also unhelpful, although its injection into animals will sometimes cause the formation of specific agglutinins and thus betray the presence and identity of the organism despite its being dead

STAPHYLOCOCCAL FOOD POISONING

This recently recognised form of food poisoning is more entitled to be so described, since a bacterial poison or toxin is its sole cause

Ætiology.—Some strains of *Staphylococcus pyogenes aureus*, in addition to the various toxins which operate when they cause boils and carbuncles, osteomyelitis and pyæmia, etc., form an enterotoxin This is liberated during their growth in food-stuffs these may be either milk, ice cream or cheese, or—as in several recent extensive outbreaks—meat Such meat has usually been handled (literally) by a cook or factory employee who either has a staphylococcal infection of a finger or carries staphylococci in his nose, whence they can be transmitted by the air or manually to any material with which he works The operation of preparing cold meats such as pressed beef, as ordinarily carried out, involves extensive handling The staphylococci then multiply either in the meat itself or in the jelly or “glaze” surrounding it Four simultaneous outbreaks in the summer of 1948, one involving passengers in the *Flying Scotsman*, the others in London and towns in eastern and southern counties, were all traced to an establishment where meat was so prepared Both operatives engaged in this work were carriers of staphylococci proved by phage typing to be identical with those recovered from samples of incriminated meat and from the vomit of affected persons

Symptoms.—Vomiting, which may be frequent and prostrating, begins within 2 to 4 hours of consuming the responsible food There is also usually diarrhoea, but this is a less prominent feature than the vomiting, and fever is absent The condition is thus quite distinct from *Salmonella* infection or intoxication Recovery begins within 24 hours and only symptomatic treatment is possible or necessary

Diagnosis.—The occurrence of severe vomiting in a group of people who have all partaken of the same meal a few hours before is strongly suggestive of this diagnosis. Its verification depends on the fact that very large numbers of staphylococci are present in the food they can be cultivated from it and from the vomit of sufferers The mere presence of large numbers of pathogenic staphylococci is almost certain proof of the nature of the condition, and their identification by phage typing as belonging to a type known to form enterotoxin may be taken as settling the matter

Direct proof that an individual strain forms enterotoxin has hitherto demanded tests in human volunteers or monkeys, although a less satisfactory one can be done in kittens, but there is recent evidence that an *in vitro* test depending on the contraction produced in a strip of animal intestine may serve instead

BOTULISM

This fortunately rare and frequently fatal form of food poisoning is also caused by a pre-formed bacterial exotoxin, with the important difference that the toxin is absorbed and acts elsewhere in the body. In this feature the disease is unique, no other bacterial toxin can be absorbed from the alimentary tract, although others act there locally.

Ætiology.—The responsible organism is *Clostridium botulinum*, an anaerobic spore-forming Gram positive bacillus belonging to the same genus as the species causing tetanus and gas gangrene. Such organisms are widely distributed in soil, and the presence of some of them there is attributed to manuring, since they also occur in the faeces of animals, including man. On the other hand, some at least must be regarded as primarily soil inhabitants and occurring only accidentally in the mammalian alimentary tract. This seems particularly true of *Cl. botulinum*, since it is rarely demonstrable in faeces and occurs in virgin soil from remote areas as well as that from cultivated land. Its presence has been demonstrated in samples of soil from various part of England as well as the United States and other countries, and in view of this wide distribution the rarity of the disease is at first sight surprising. Two types, designated A and B, the former being much commoner, and producing different toxins, cause human botulism. Several other types exist which cause similar diseases in animals.

Growth of *Cl. botulinum* is only possible under anaerobic conditions—*i.e.*, in the complete or almost complete absence of oxygen. These conditions are attained when food is canned or bottled; they may also exist in the interior of a mass of meat, such as a ham. Commercial canned and bottled products are subjected to temperatures which destroy even the spores of Clostridia, home canning is a less safe procedure and its prevalence in the United States accounts for the greater frequency of botulism in that country than in ours. If many spores of *Cl. botulinum* are present (small numbers are less likely to germinate) and survive the heat treatment applied they will subsequently multiply and during their growth the exotoxin is formed. The food may be meat, fish or vegetable (commonly string beans, peas, corn and spinach have also been affected), fruits, the juice of which is acid, do not usually permit growth. "Spoilage", *i.e.* alterations in colour, consistency, smell and taste ending in frank putrefaction, will eventually result, and it seems that the rarity of botulism may be due in part to the fact that only a short period may elapse between the beginning of toxin formation and the development of changes which should at least excite suspicion if they do not render the food quite unpalatable.

The toxin of *Cl. botulinum* is by far the most powerful poison known. 1 gramme of it would furnish a lethal dose for many millions of people. It is a protein, and readily denatured by heat, hence food containing it can be rendered innocuous by re-cooking. It is absorbed from the alimentary tract and exerts its effects on the nervous system.

Symptoms.—The onset may be early on the day following the responsible meal or delayed for up to 48 hours. Vomiting is inconstant, but commoner when the onset is earlier and hence the amount of toxin swallowed presumably larger. Diarrhoea is also inconstant and never pronounced or persistent; constipation is more common. The earliest characteristic symptoms are diplopia and unsteadiness on standing; these are accompanied by fatigue, dizziness and muscular weakness. There is no fever and little or no headache. What follows is the result of the paralysis first

of the motor cranial nerves no sensory changes occur. All the ocular muscles are affected, complete ptosis depriving the patient of sight. The tongue cannot be protruded and the power of speech and of swallowing are eventually lost. Paralysis may then extend to the diaphragm and intercostal muscles, the dorsal muscles of the neck and the arms. Full consciousness is retained, and the plight of a patient struggling for breath and unable to see, speak or swallow, is described as pitiable. Death may occur after as long as 7 days, or may result apparently from cardiac failure within 24 hours before difficulty in respiration has developed. The mortality in different outbreaks has varied but is always high and sometimes 100 per cent.

Treatment—The only specific measure is the administration of antitoxin which should be polyvalent (i.e. containing antitoxins for both types, A and B). Since the Loch Maree disaster of August 1922, when all 8 members of a fishing party provided with sandwiches made of potted wild duck paste died of botulism, stocks of this antitoxin have been maintained at centres in different parts of the British Isles. Only one small outbreak and one other isolated case have been recognised since then; hence there has been little opportunity to use the antitoxin, and such use as has been made was ineffectual. It is an axiom that antitoxins, although fully effective in prevention, are effective in treatment only if given early, before toxin has done irreparable damage. The likelihood of early administration in so unfamiliar a disease is small.

The supposed value of giving alcohol to de-nature unabsorbed toxin is doubtful. Morphine is indicated for the relief of distress and is also said to delay the progress of the disease. In protracted cases fluid should if necessary be supplied rectally or intravenously. A respirator should be used if paralysis of respiratory muscles develops, but it is doubtful whether recovery is possible after this stage.

CL. WELCHII FOOD POISONING

It has recently been recognised that *Clostridium welchii*, strains of which are the commonest cause of gas gangrene, can also cause food poisoning, apparently of two forms. Both are due to types of this organism which are exceptionally resistant to heat. The spores of *Cl. welchii* are in general much less heat resistant than those of other species, and are destroyed by boiling or steaming for 10 minutes. The food poisoning types are not, and can thus be easily recovered from food or faeces steamed for 1 hour.

The mild form, of which there have been many outbreaks in recent years, has invariably been caused by meat or meat preparations which have been cooked, allowed to cool slowly and not refrigerated, and eaten a day or more later. This practice was less common before the war, as was the provision of meals in canteens where the occurrence of food poisoning is much more likely to be recognised and investigated than in the home. The growth of the organism which is a feebly toxigenic and otherwise atypical type A, usually causes no detectable change in the meat. The results of its consumption are simply colic and diarrhoea, without vomiting or headache, beginning 8 to 20 hours after consumption and lasting no more than a day.

The other form, which is severe and often fatal, has been described chiefly in Germany, produced in some cases by home-canned meat such as rabbit, and is known as enteritis necroticans. It is a diffuse enteritis involving especially the jejunum but also the ileum and colon in which acute inflammatory changes with marked oedema of the mucosa are followed by necrosis of its superficial layers and hence the formation of sloughs. The onset is abrupt, with severe pain, some abdominal rigidity, vomiting and profuse diarrhoea leading to dehydration and circulatory collapse. The mortality is high. The responsible organism is *Cl. welchii* of type F, forming a large amount of toxin.

LAWRENCE P. GARROO

UNDULANT FEVER OR BRUCELLOSIS

Synonyms.—Malta or Mediterranean Fever, Abortus Fever, Brucellosis.

Definition.—An endemic or epidemic disease characterised clinically by prolonged fever with a tendency to long wavy relapses, splenomegaly, transient painful swellings of the joints, neuralgia and secondary anaemia. In Malta *Brucella melitensis*, conveyed in goats' milk, proved the causative organism, but indistinguishable diseases of widespread geographical distribution may be caused by the bovine and porcine strains of *Br. abortus*.

Ætiology.—Undulant fever of caprine origin is endemic in the Mediterranean basin, and has a widespread geographical distribution. The indigenous population sometimes appears to have a certain immunity to the disease as in Malta, where the Maltese, prior to the boiling of goats' milk by the garrison, were less affected than English soldiers and sailors. All ages and both sexes appear equally susceptible, and in Malta, at least, the disease proved more prevalent in the dry summer months.

Bruce, in 1886, isolated *Br. melitensis* from cases of undulant fever and experimentally reproduced the disease in monkeys. Eighteen years later it was proved that infection was conveyed in goats' milk. The organism causes a bacteraemia and may be isolated from the blood, bile, faeces, urine and milk. Primarily it is a disease of goats which, while themselves showing few symptoms, may yield a good quality milk containing large numbers of *Br. melitensis*. Other varieties include the bovine and porcine strains of *Br. abortus*, and are only distinguishable by agglutinin absorption tests. The latter organism, which infects the chorionic cells, causes contagious abortion of swine and cattle, and produces a disease in man indistinguishable from undulant fever; it has been reported from the United States, Europe, Southern Rhodesia, South Africa, etc., is of bovine or porcine origin, and is contracted from cow's milk or contact with carcasses, infected animals or their excreta.

Pathology.—The disease is essentially a bacteraemia and organisms may be isolated from the blood, spleen and lymph glands at necropsy. The spleen is constantly enlarged, averaging about 20 oz in weight. Sometimes the mesenteric glands appear swollen, but there is no ulceration of Peyer's patches. The liver, kidneys and pulmonary bases show congestion, and occasionally broncho pneumonia and glomerulo nephritis are found.

Symptoms.—The incubation period is about 14 days, but may last a longer or shorter period. Monkeys develop fever 5 days after subcutaneous inoculation, and 15 days after ingestion of infected material. Five clinical varieties are recognised.

(1) Ambulatory, (2) Undulant, (3) Intermittent, (4) Continuous, and (5) Malignant.

(1) **AMBULATORY OR MILD.**—In some cases the symptoms are so slight that infected persons go on with their work as usual, in others there are slight fever and minor symptoms which disappear rapidly, serum tests alone indicating infection. Out of 525 dock hands examined by Shaw in Malta, 79 gave positive agglutinin reactions, whilst 9 out of 22 of those specially tested showed the organism either in the blood or urine or both. Such cases constitute human carriers.

(2) **UNDULANT OR ORDINARY.**—The onset is generally insidious like typhoid, and the symptoms often resemble those seen in other fevers, but the temperature chart is characteristic. Bouts of fever lasting 2 or 3 weeks alternate with periods of remission, so producing the typical undulant fever chart. Illness in the ordinary case lasts 3 to 4 months, the extremes being 3 weeks to 2 years. The fever is often associated with profuse sweating, lassitude, secondary anaemia, debility and transient painful swelling of the joints resembling rheumatic fever, but not responding to salicylates. Enlargement and tenderness of the spleen and liver also occur, and neuralgic pains, especially involving the intercostal and sciatic nerve, are common. The tongue frequently has a central white fur, and anorexia, flatulence, abdominal discomfort

and constipation are often troublesome features. The leucocyte count is generally normal, but there is a relative lymphocytosis, the urine may contain albumin. After running a more or less chronic course, the remissions become more prolonged, the febrile exacerbations less high, and recovery gradually ensues. No patient should be regarded as convalescent, however, until the temperature and pulse have been normal for at least a fortnight and all other symptoms have disappeared. Neuritis, debility and anaemia may persist for a considerable period.

(3) **INTERMITTENT TYPE**—There is a swinging temperature resembling benign tertian malaria, a normal morning temperature being succeeded by a sudden afternoon rise to 105° F or higher, accompanied by chilliness and a definite rigor, by evening the temperature falls again with drenching sweats. The condition is differentiated from malaria by the absence of parasites.

(4) **CONTINUOUS TYPE**—Here there is continuous fever for a period of from 1 to 3 months.

(5) **MALIGNANT TYPE**—The patient is attacked suddenly with high fever, severe generalised pains, diarrhoea and vomiting. Broncho pneumonia, cardiac weakness and a typhoidal state frequently develop, while hyperpyrexia may precede death.

Complications—These include bronchitis, broncho pneumonia, neuritis, parotitis, orchitis in the male and mastitis in the female. Purpura and suppurative osteitis have also been described. Menorrhagia, abortion or premature labour may also result.

Diagnosis—The differential diagnosis includes the enteric fevers, acute rheumatism, malaria, kala azar, tuberculosis, subacute bacterial endocarditis, thoracic lymphadenoma associated with the Pel-Ebstein syndrome, amebic abscess of the liver and occult pyogenic infections. Macroscopic agglutination reactions are of great diagnostic value after the first fortnight of fever, the serum being tested in an ascending series of dilutions (1/25–1/1000) against dead *Brucella* suspensions. Absorption of agglutinin may be necessary to distinguish infections with *Br. melitensis* and *Br. abortus* respectively. Blood culture in liver infusion broth is often positive for *Br. melitensis*, and the period of examination should extend over a fortnight before reporting the result as negative. *Br. abortus* is best grown in an atmosphere of 10 per cent carbon dioxide or, better still, 1 ml of suspected blood is inoculated into the peritoneal cavity of a guinea pig, culture from the peritoneal cavity being generally positive in about a week and from the spleen at a later date. Burnet's intradermal test is frequently positive, it is characterised by the development of localised redness and oedema some 6 hours after inoculation, the reaction lasting 1 to 2 days.

Prognosis—Mortality rates of from 2 to 9 per cent have been recorded. Death generally results in malignant cases during the first 3 weeks of fever. At any time, however, fatal recrudescence may occur, a typhoidal state, broncho pneumonia, cardiac failure and hyperpyrexia being grave signs. Chronic cases may present great debility, emaciation, anaemia and neuritis.

Treatment—**PROPHYLACTIC**—Laboratory workers should be very careful in handling *Brucella* cultures for, as in tularemia, infection is easily acquired. Adequate boiling of goats' milk renders it safe, but its prohibition in endemic centres and the destruction of infected animals are more effective. Cream and cheese may also convey infection. In the case of *Br. abortus* the disease may arise from cows' milk or the carcasses or excreta of bovines and porcines.

CURATIVE—Careful nursing and a nourishing dietary which should include milk puddings, eggs, fish, fruit juice, yeast and other vitamin-containing foods are desirable. Cool sponging is indicated whenever the temperature exceeds 103° F. Specific therapy is still under trial. Autogenous vaccines, brucellin, anti undulant fever serum and immune transfusion of compatible blood from a recovered case are all of doubtful value. A course of sulphonamide terminates the fever in some cases, but recurrences are frequent. Recently the administration of small doses of sulphadiazine

or sulphamerazine combined with blood transfusion has been advocated. Cures are recorded following T.A.B. vaccine intravenously, commencing with 50 millions and working up to 250 millions, injections being given every fourth day. Promising results are now being reported following combined treatment with a full course of sulphadiazine and streptomycin. The course lasts for 10 days, 2.0 g. of streptomycin being given in divided doses each day. Penicillin is ineffective. The best antibiotic seems to be chlortetracycline given in doses of 0.5 g. 6-hourly for 10 days. This treatment quickly arrests the clinical attack but is likely to be followed by relapses, which require repetition of treatment.

Various symptoms and complications, such as sleeplessness, headache, arthritis and orchitis, should be treated as they arise.

PLAGUE

Synonyms.—Oriental Plague; Pest; Black Death.

Definition.—Plague is primarily a disease of rodents caused by the *Pasteurella pestis*. Transmitted to man by rat fleas, it runs a rapid course with high fever, and a marked tendency to septicæmia and tender enlargement of lymphatic glands. More rarely a pneumonic form develops.

Ætiology.—Plague may occur anywhere; it is more common in subtropical regions, but towards the equator tends to die out. High temperatures and a dry atmosphere or high saturation deficiency reduce its incidence in the hot weather in India by killing the flea vector. It spread from Hong Kong to India, Egypt and Japan in 1896, and three years later to the Philippines and South America. People of any race, age or sex are susceptible. The plague bacillus, *Pasteurella pestis*, was isolated by Kitasato and Yersin in 1894. It is readily cultured, and is a short, Gram-negative rod showing bipolar staining. Guinea-pigs and other laboratory animals are susceptible. Rat fleas, especially *Xenopsylla cheopis*, which have fed on the blood of infected rodents such as the large grey rat (*Rattus norvegicus*) and the smaller black rat (*Rattus rattus*), desert these animals after death and inoculate man by regurgitating *P. pestis* during the act of biting and sucking blood. Epizootics in rats invariably precede human epidemics, and an extension of plague to man can be accurately foretold 2 or 3 weeks beforehand from a rising curve of infection in the rat population. Pneumonic plague, on the other hand, is intensely infectious, being directly transmitted by droplet spray infection from person to person. Doctors and nurses often acquired the disease during the Manchurian epidemic.

Pathology.—At the site of entrance, especially in resistant cases, plague bacilli may occasionally produce a primary vesicle. Generally the adjacent chain of lymph glands are acutely inflamed (primary bubo) while others are secondarily involved. Frequently bacilli enter the circulation, producing various degrees of septicæmia and in the most fulminating cases primary buboes may be absent altogether. The toxic substances elaborated by *P. pestis* also affect the endothelial lining of the blood vessels, giving rise to congestion and hæmorrhage in the mucous and serous membranes and skin, while the cardiac muscle shows fatty degeneration and the right heart is dilated. On section the primary bubo shows intense congestion and hæmorrhage, with periglandular, gelatinous and hæmorrhagic œdema matting adjacent glands together. More distant glands, secondarily implicated, are congested and greyish red in colour. Bacilli are numerous in the early stages and also often occur in the spleen and blood. The liver and kidneys are congested, showing cloudy swelling and fatty change, and fibrinous thrombi may be present in the Malpighian tufts. The spleen, which is two or three times its normal size, is hyperæmic and often hæmorrhagic. The meninges are very congested and hæmorrhages may occur in the brain. Pneumonic plague starts as a broncho-pneumonia, but later may involve the

entire lobe; pleural ecchymoses, congestion of the bronchial tree and involvement of the bronchial glands are characteristic

Symptoms.—The incubation period varies from 2 to 12 days, generally being 3 to 4 days. In severer infections there is a marked tendency towards septicæmia and in the types of *pestis* major a sudden onset with chill or rigors, irregular high fever, nausea, vomiting, cardiac weakness and great mental prostration is characteristic. Splenomegaly and also hæmorrhagic rashes may occur, hence the ancient synonym "black death". Nine clinical types have been described

(1) **BUBONIC**—Prodromata include backache, pains in the limbs, and mental depression, but generally the onset is abrupt and the constitutional features severe. The blurred speech, reeling gait and mental dullness may suggest alcoholic intoxication. Examination reveals fever, injected conjunctivæ, rapid soft pulse, the urine contains albumin and the blood count shows a moderate leucocytosis. On the second or third day a tender primary bubo appears, the affected group of glands (femoral and inguinal=70 per cent, axillary=20 per cent, submaxillary and cervical=10 per cent) rapidly swelling to the size of a hen's egg or larger. Pain is severe and suppuration generally occurs during the second week. Death usually eventuates between the third and fifth day, with recovery the symptoms gradually ameliorate, but convalescence tends to be protracted. Secondary broncho-pneumonia may occur, and the sequelæ include sepsis, carbuncles, etc.

(2) **SEPTICÆMIC**—The disease is rapidly fatal, there may be splenomegaly and slight general enlargement of lymphatic glands, but no bubo. Frontal headache, fever and vomiting are characteristic, but in the severest cases there may be only a slight rise of temperature. Cutaneous petechiæ and melana may be noted. The diagnosis is made by a positive blood culture.

(3) **PNEUMONIC**—Chill and a rapid rise of temperature occur at onset, followed by headache, dizziness, pains in the limbs, clouding of consciousness, pain and tightness in the chest, with cough and expectoration of a copious, sanguineous, watery sputum teeming with plague bacilli. Dyspnoea with cyanosis, crepitations and possibly areas of diminished resonance are found. Cardiac failure is common and death almost invariably occurs within 4 days.

(4) **INTESTINAL**—A rare form, described by Wilm in the Hong Kong epidemic of 1896, as an intestinal disorder with vomiting, incessant purging and liquid, offensive, bile stained stools often mixed with blood. Buboes were absent, but pathological lesions were present in the intestine.

(5) **CEREBRAL**—In this type, which may resemble cerebral malaria, the mental hebetude characteristic of ordinary bubonic plague progresses to delirium, convulsions and coma. Definite plague meningitis has also been recorded, and may run a chronic course.

(6) **CELLULO CUTANEOL**—Carbuncles appear having a necrosed and ulcerated centre, with a hard edge surrounded by a red areola, sometimes covered with minute vesicles. The condition is distinguished from coccal carbuncle by the demonstration of *P. pestis*.

(7) **VESICULAR OR VARIOLOID**—In this form the vesicles and pustules may be so abundant as to simulate varicella. *P. pestis* is readily isolated from the vesicles.

(8) **ANGINAL OR TONSILLAR**—Cervical buboes may implicate the tonsils, or violent plague tonsillitis and pharyngitis, with secondary cervical adenitis, may arise from killing vermin with the teeth—a habit of Indians in Ecuador.

(9) **ABORTIVE OR AMBULATORY (*Pestis minor*)**—Such cases are common in all epidemics. Buboes develop and may suppurate or be absorbed without serious indisposition or fever, or the lymph glands may simply swell and become painful, associated with transient headache.

Complications.—Acute bubonic cases may develop plague septicæmia or pneumonia with fatal results, or after the fever has disappeared the local buboes may

become indolent and take many weeks to heal. Broncho-pneumonia and septic complications such as subcutaneous abscesses, cellulitis, adenitis and parotitis sometimes ensue.

Diagnosis.—Bubonic plague early in an epidemic may need to be differentiated from climatic bubo, chancreoid or syphilitic buboes, rat-bite fever and possibly tularemia. Gland puncture reveals bipolar bacilli on culture or in smears, the crucial test being transmission of plague to the white rat by smearing infective material on its skin. In pneumonic plague herpes is absent and the sputum is sanguinolent and watery, not viscid and rusty as in pneumonia: furthermore it is teeming with plague bacilli. Septicæmic plague is diagnosable only by positive hæmo-culture.

Prognosis.—Pneumonic and pure septicæmic plague have in the past been practically always fatal. In bubonic plague the mortality rate was much higher in natives (75 to 80 per cent.) than in Europeans (25 to 30 per cent.) and axillary buboes were less favourable than inguinal ones. Positive hæmo-culture is of serious significance, and Liston showed that where the bacilli exceed 40 per 1 ml. of blood, death almost invariably resulted.

Modern chemotherapy is very effective in all forms of plague, including pneumonic.

Treatment.—**PROPHYLACTIC.**—This consists essentially in the destruction of rats and fleas, in preventing their coming into contact with man, and in increasing individual resistance by Haffkine's prophylactic vaccine, which gives an immunity lasting 6 to 12 months or more. The building of ratproof houses and grain stores, rat destruction by poisoning and trapping, fumigation of ships with sulphur dioxide and hydrocyanic gas, and evacuation of infected villages and houses during epidemics are all important measures in controlling the spread of plague. Fleas are killed by a dust containing 10 per cent. of D.D.T.; this is best applied to rat runs by a pressure sprayer.

Overalls, masks, caps and gloves should be worn by those dealing with plague cases. D.D.T. impregnated clothing reduces the risk of flea bite.

Contacts of pneumonic cases should be isolated and watched. Successful chemoprophylaxis has recently been achieved. Adults who have been in intimate contact with cases receive 6 g. sulphadiazine daily for 3 days to 1 week after contact; others may be given 3 g. daily for the same period. Contacts of bubonic cases should also receive chemoprophylactic treatment.

CURATIVE.—Bed rest, liquid diet and careful nursing are essential. The buboes should be treated by hot fomentations, kaolin poultice or belladonna and glycerin applications with incision if suppuration occurs. Morphine may be necessary for the pain. Stimulants and cardiac tonics should be used early, and intravenous injections of dextrose are of value. Specific treatment, with large doses of antiplague serum intravenously during the first 2 days has reduced the mortality. Favourable results ensue from treatment with sulphonamides, particularly sulphamerazine, sulphadiazine and sulphathiazole. Examples of dosage régimes are: *sulphadiazine* orally, 4.0 g. immediately; 2.0 g. after 4 hours; 1.0 g. every 4 hours until temperature has been normal for 2 days. Some workers recommend continuing a dose of 0.5 g. 4-hourly for up to 10 days. *Sulphamerazine* intravenously, 2.5 g. in 50 ml. of 5 per cent. glucose solution at 8-hourly intervals for three doses, followed by two further injections containing 1.5 g. each at 8-hourly intervals and then 1.0 g. orally every 8 hours. When sulphonamides are given, abundant fluids are administered, the urine is kept alkaline by the oral administration of bicarbonate of soda and citrates, and a careful record is kept of the urinary output during each 24 hours; this should not be permitted to fall below 50 oz.

Streptomycin is effective alone or in combination with one of the above sulphonamides. The following régimes have been used successfully:

(a) *Streptomycin* intramuscularly, 0.66 g. immediately; 0.33 g. every 4 hours night and day until the temperature has been normal for 1 or 2 days. Very severe

cases may be given 0.66 g. 4-hourly until the temperature has been normal for 2 days.

(b) *Streptomycin* intramuscularly, 0.25 g. to 1.0 g. every 4 hours until temperature is normal. *Sulphadiazine* given orally concurrently, 4.0 g. immediately; 2.0 g. 4 hours later; 1.0 g. every 4 hours subsequently until the temperature has been normal for 2 days.

Pruritus and urticaria may occasionally complicate streptomycin injections, but serious toxic effects have not been described.

N. HAMILTON FAIRLEY.

TULARÆMIA

Synonyms.—Deer-fly Fever; Pahvant Valley Fever; Ohara's Disease.

Definition.—A plague-like general infection of small rodents, hitherto confined to the United States, Japan and a district in Siberia; also recently in Norway, communicable to man. The disease has the peculiarity, in which it resembles Malta fever, of being extremely infective to laboratory workers handling the causative organism, *Brucella tularensis*.

Ætiology.—In 1911 M'Coy, during plague work among ground squirrels in California, discovered a plague-like disease not due to *Pasteurella pestis*, and in 1912 M'Coy and Chapin isolated the specific organism from the blood of infected animals, and it was named *Bacterium tularense*. Subsequently the organism was found in various rodents, and endemic centres of the infection have been recognised in many areas of North America. The first human case of infection appears to have been reported by Pearse in 1910, but bacteriological proof connecting it with *Br. tularensis* was provided by Francis subsequently. Where the infection is endemic among rodents, human cases are not uncommon, and possibly some have recovered unrecognised. The infection is conveyed from animal to animal by various blood-sucking parasites. The fæces of infected bugs have been shown to be infective. Polluted water has recently been thought to be a source of infection in Norway and U.S.A. There is thus no difficulty in understanding how endemic centres of infection are kept up, and human infections in the field are readily understood. But it is difficult to explain the cases of infection in laboratory workers. It is suggested that a possibility is respiratory infection during the anæsthetising of experimental animals, when coughing is not uncommon, and the bacillus is certainly contained in bronchial secretions, as well as the excreta generally. The question appears to be parallel to

Laboratory workers studying the infecting agent have suddenly developed pyrexia, with marked malaise and often evidence of pneumonia or pleurisy. The temperature subsided at the end of 3 weeks. The marked features of the majority of the cases were the malaise, the recurrent nature of the fever and the prolonged inability to work. Neuroglandular, oculoglandular, glandular and typhoid forms of the disease have been described.

Diagnosis.—In endemic areas, people handling rabbits and other rodents, who develop fever, with or without localising signs of insect bites, should be under suspicion. In this country, only laboratory workers are likely to be infected. In either case, the diagnosis depends upon specific agglutination of *Br. tularensis* antigen. Very definite agglutinations were noted towards the end of the second week after the commencement of the disease, and the titre rose rapidly and remained high during the long convalescence. *Br. tularensis* can usually be obtained by inoculating rabbits or guinea-pigs intraperitoneally with 1 or 2 ml. of blood or other infected material.

Prognosis.—The mortality rate varies with the clinical type of infection from about 4 per cent in the ulceroglandular form to 50 per cent in the typhoid variety. These figures date from before the introduction of streptomycin and chlortetracycline.

Treatment.—Various antitularæmic sera have been employed with doubtful results, but the use of streptomycin and more recently of chlortetracycline has completely altered the outlook in this disease. Administration of either of these antibiotics is followed by rapid subsidence of fever, disappearance of constitutional symptoms and recovery.

GLANDERS

Definition.—An infectious disease, occurring not infrequently in the horse and in the ass, occasionally transmitted to man, and characterised by the formation of granulomatous nodules in the nose (glanders), and in the subcutaneous tissues (farcy).

Ætiology.—The *bacillus of glanders*, or *Pfeifferella mallei*, is a short rod, straight or slightly bent, of 3 to 4 μ in length by 0.5 to 0.75 μ in thickness. It is non-motile, and possesses no flagella, nor does it form spores. It can be cultivated on ordinary media at 37° C, but gives a more characteristic growth on potato.

The bacillus stains somewhat faintly with the usual aniline dyes, so that a mordant, such as carbolic acid, is usually employed, but even when deeply stained there is a tendency to decolorise rapidly. The staining is markedly irregular, this irregularity being a diagnostically helpful point. It is Gram-negative.

Pathology.—The disease chiefly affects horses, mules and asses—the latter being the most susceptible. Horned cattle are immune, but goats and sheep are occasionally infected.

In the horse, infection may take place through any abrasion of the skin, but most frequently through abrasion of the nasal mucous membrane from infected water-troughs or feeding-mangers. The infection may be acute or chronic. In the acute form (glanders proper) there is fever and prostration, and in 2 or 3 days there occurs ulceration of the nasal mucosa with a sero-purulent discharge, leading on to involvement of the lungs, and death within a few weeks. In the chronic form—farcy—there is involvement of the lymphatic system associated with the original site of entry. The lymph vessels become enlarged—farcy pipes—and irregular thickenings—farcy buds—occur, which may soften and suppurate.

The disease may be latent, and can then only be diagnosed by the "mallein" test. In the human being the infection is generally derived directly from the horse, and is therefore usually confined to those in close connection with horses, but the disease has been contracted in the laboratory.

The toxin of *Pf. mallei* or mallein is an endotoxin, being derived from the bacterial

bodies, in which respect it differs markedly from the toxins of tetanus and diphtheria bacilli. One of its chief characteristics is its resistance, it being capable of withstanding temperatures of 120°C and prolonged storage with but little loss of strength. It is prepared by growing cultures in glycerin broth for 3 or 4 weeks, and sterilising these by boiling or autoclaving at 115°C . The cultures are then allowed to stand and the supernatant fluid being decanted off, this is then filtered through a Chamberland filter. The resultant filtrate, to which one half of 1 per cent of carbolic acid is added, constitutes *mallein*. It contains the soluble portions of the bacteria, and substances from the altered medium, and is a similar product to tuberculin. It is used in doses of 1 ml to detect a glanders infection in the horse. As the reaction in a "glandered" animal is severe, both locally and constitutionally, it is unsuitable for use in man.

FORMS OF THE DISEASE—Both glanders and farcy have been known to occur in man in acute and in chronic forms. All forms are rare.

Symptoms—1 **ACUTE GLANDERS**—The incubation period varies, but is in most cases 4 days. At the site of infection in the nose there occurs an inflammatory swelling surrounded by œdema and lymphangitis, with a papular eruption soon becoming pustular. In a few days other and similar swellings appear, which soften and ulcerate, so that the mucosa of the nose becomes generally infected, leading to profuse mucopurulent discharge. The whole nose swells, sometimes considerably. The ulceration extends deeply so as to involve the cartilage and bone. The cervical lymph nodes are usually enlarged and may soften, forming abscesses. Constitutional symptoms are present by this time, and death, usually with pneumonia, occurs about the middle of the second week.

2 **CHRONIC GLANDERS**—This form resembles closely the disease as seen in the horse. There is a chronic profuse coryza, associated with widely scattered muscular and subcutaneous nodules. Unless the nature of the disease is suspected, it may go undiagnosed for some time.

3 **ACUTE FARCY**—This is the form of the disease resulting from accidental inoculation of the skin. A local lesion of a highly inflammatory kind leads quickly to a spreading zone of lymphangitis, subcutaneous nodules (farcy buds) appearing in the track of the infection, softening and forming abscesses. The patient becomes severely ill, with symptoms of a general infection, and the course of the disease is of much the same duration as in acute glanders.

4 **CHRONIC FARCY**—This only differs from acute in that the "buds" are associated with much less inflammatory reaction, the constitutional symptoms are much less severe, and the course of the disease is much longer. A few of the cases have extended over 12 months.

Diagnosis—Acute glanders has been mistaken for small pox, owing to the likeness of the papulo-pustular eruption to the specific eruption of this disease. The chronic forms are at times mistaken for the other infective granulomata (syphilis, tuberculosis and actinomycosis). Exact diagnosis turns upon bacteriological methods direct or indirect.

The *bacteriological diagnosis* in man may be simple if a superficial swelling exists which may be opened. Direct cultures may be made therefrom, preferably on potato and a rapid diagnosis made. It may be, however, that weeks elapse before such an opportunity occurs, or before some deeply situated swelling calls for operative interference, in such cases serum reactions, such as the complement-fixation test and agglutination are indicated.

If material containing *Pf. mallei* be injected intraperitoneally into a male guinea-pig, tumefaction and suppuration occur in 2 or 3 days in the tunica vaginalis, and the bacilli can be recovered therefrom after about 6 days.

Treatment—**PROPHYLACTIC**—The utmost care must be taken in nursing, destruction of old dressings, etc.

The site of inoculation, if obvious, should be excised, and the underlying tissues should be treated drastically by strong antiseptics. All abscesses should be opened promptly and efficiently drained. The general symptoms are met by treatment similar to that given in any septicaemia. Experience with chemotherapy and the antibiotics has been limited on account of the rarity of the disease, sulphadiazine was thought to have some effect in six patients and the recovery of another was attributed to streptomycin.

R BODLEY SCOTT

MELIOIDOSIS

Definition—A fatal disease, resembling glanders in symptoms and pathology, caused by *Pfeifferella whittmori*, it has been found in Burma, British Malaya, Cochin China and Ceylon, and is primarily a disease of rodents, the mode of human infection is unknown.

Pathology—The characteristic lesions are small caseous nodules which sometimes coalesce, forming large honeycombed abscesses in the viscera. The lungs, liver, spleen and, less commonly, the intestines and kidneys may be implicated, while pustules and bullae may involve the skin. *Pf whittmori* is readily cultivated from these lesions as well as from the blood during the septicaemic stage, but the safety-pin like bipolar staining organisms are scanty in smears of the pus obtained from the nodules.

Symptoms—In severe cases the vomiting, purging and collapse may simulate cholera, and death from septicaemia may occur in 3 days, other cases may show remittent and intermittent pyrexia for weeks and months. The clinical picture varies with the organ predominantly attacked, and according to Stanton and Fletcher the clinical types may resemble (1) plague, (2) broncho-pneumonia, (3) typhoid or malaria, (4) liver abscess, (5) infective endocarditis or general tuberculosis, (6) pyelitis.

Diagnosis—This is always difficult clinically, and is dependent on the cultivation of the organisms from the blood, sputum, urine, cerebrospinal fluid or material aspirated from the liver or spleen. Relatively few cases have been diagnosed during life.

Treatment—Food should be protected from contamination by rats and other rodents. In man the disease is almost invariably fatal. Autogenous vaccines are worth a trial, but neither vaccines nor anti sera possess protective power in infected animals.

CHOLERA

Definition—A specific disease due to Koch's comma vibrio, characterised clinically by violent vomiting, painless diarrhoea with copious rice-water stools, dehydration, muscular cramps, aphonia, collapse and urinary suppression.

Ætiology—Cholera exists endemically in India, China and certain other Far Eastern countries. In India Rogers demonstrated three main endemic foci from which epidemics spread in the spring and summer through mass movements of pilgrims who acquired the disease from infected water. War may lead to the spread of cholera and herding of people in famine and prison camps also favours outbreaks. Occasionally cholera has reached Europe. People of different race, sex and age are all susceptible.

The causative organism is *Vibrio cholerae*, described by Koch (1883). The true cholera vibrio (1) ferments mannose and sucrose but not arabinose, (2) does not hemolyse goat's erythrocytes and (3) agglutinates with O group 1 serum. The status of the hemolytic El Tor and Celebes strains of vibrio remains undecided. Water

transmission is an important mode of spread. When the general water supply becomes infected, as in the Hamburg epidemic (1892), a sudden widespread outbreak follows. If wells or other local water supplies are infected, cases appear from day to day in the locality so supplied. Flies also may disseminate the disease by contaminating food, milk, etc., with infected faeces. Cholera vibrios occur in great numbers in the rice-water stools, but disappear rapidly. Both the cholera convalescent and the contact carrier lose their vibrios within a few days of the termination of the attack or contact with a cholera case. Chronic carriers, as in typhoid fever, are unknown, and the actual cholera patient remains the main source of spread. Cholera-phage is said to be absent from the stools of the most virulent cases, and present in mild and convalescent ones.

Pathology.—After death rigor mortis sets in early. The blood is thick and tarry. The small intestines are collapsed and shrunken, the mucosa is denuded of its epithelial lining, congested and perhaps hæmorrhagic, and the lymphoid follicles are enlarged. The stomach and liver are congested, and the gall-bladder distended with viscid thick bile, difficult to expel—hence absence of bile in the intestine. The kidneys show swelling, congestion and ecchymoses, the spleen is small and shrunken and the lungs collapsed and dry.

The cholera vibrio is readily isolated from the contents of the small intestine and occasionally from the gall-bladder. The vibrios undergo disintegration on the surface epithelium, especially of Lieberkühn's glands, with liberation of a powerful endotoxin. Denudation of intestinal epithelium, outpouring of fluid from the blood vessels into the lumen of the bowel and absorption of toxin into the circulation result. Toxæmia and fluid loss underlie the pathological findings and clinical picture. Diarrhœa and vomiting lead to chloride depletion, to decrease in blood volume with increased viscosity of the blood and to tissue dehydration. Biochemical investigations show reduced blood chloride, diminished plasma alkalinity, phosphate retention and increased blood urea. A polycythæmia of 6 to 8 million red corpuscles per c.mm. and a leucocytosis of from 15,000 to 30,000 per c.mm. are frequently found; hæmato-crit estimations have shown an average loss in serum of 35 per cent. in mild and up to 64 per cent. in severe cases. Dehydration associated with increased viscosity of the blood frequently leads to cardiac and peripheral circulatory failure; renal anoxia (cortical ischæmia) is probably the main basis of the anuria.

Symptoms.—The incubation period is 2 to 5 days.

Five clinical types have been described. (1) *Ambulatory cases*. (2) *Choleraic diarrhœa*. (3) *Cholericine*: the patient suddenly develops severe abdominal pains, passes numerous faeculent motions, then typical rice-water stools, followed by rapid recovery. (4) *Cholera sicca*: the patient becomes rapidly collapsed and dies before the typical gastro-intestinal features develop. (5) *Cholera gravis*: typical cholera, constituting 95 per cent. of the cases in most epidemics. Premonitory symptoms are frequently absent but occasionally there may be looseness of the bowels, headache, epigastric discomfort, nausea and possibly vomiting some 24 hours before true choleraic diarrhœa develops. In the ordinary severe case these stages may be

and becomes restless and exhausted. The skin is cold and wrinkled, the lips and lobes of the ear bluish, the face appears pinched, the conjunctivæ are injected, the eyeballs sunken and the voice husky and weak. Aphonia often supervenes. The respirations become rapid, the blood pressure lowered, the peripheral veins depleted and collapsed and the pulse almost imperceptible. Though the skin temperature is subnormal, in the rectum it may reach 101° to 104° F.

2 Algid or collapse stage. In this stage the vomiting and purging lessen or cease, but symptoms of collapse increase. Circulatory failure follows. Despite this, the mind generally remains clear. The cholera facies becomes even more accentuated, the skin cold, clammy and dusky, and cyanosis is marked. The pulse, which is irregular and weak, may disappear completely at the wrist. The systolic blood pressure may fall to 40 to 70 mm Hg. Cardiac sounds are weak, and a friction rub, caused by dryness of the serous surfaces, may be heard over the pericardium and pleura. Urinary secretion is markedly decreased as a result of hypotension and dehydration, and the scanty urine contains albumin and casts. Unless the low blood pressure be maintained, oliguria may be replaced by anuria. Death may occur within 3 to 48 hours of the onset of these symptoms, peripheral circulatory failure and uræmia are the most frequent causes. About 50 per cent survive this stage of collapse, and pass on to the stage of reaction.

3 Stage of reaction. With recovery, the temperature rises, the circulation and blood pressure improve, cyanosis decreases, the urinary secretion increases and the stools become feculent and contain traces of bile. Recovery may ensue within a week. In less favourable cases, especially when the collapse stage has been prolonged, a typhoid state may develop. The face is flushed, the temperature rises, the pulse and respirations are accelerated and the tongue is dry and brown, and erythematous rashes may appear and low muttering delirium ensues. The blood pressure in these cases may be elevated above normal (150 to 175 mm Hg). The cause of the syndrome is believed to be absorption of cholera or other bacterial toxin from the damaged bowel after the circulation has been restored. Fatal cases may die with hyperpyrexia. In other cases, despite circulatory recovery, urinary secretion is not re-established, no urine or only a small quantity of albuminous urine being passed. Increased respirations, Cheyne-Stokes breathing, hicough, twitching muscles, stupor, delirium, convulsions and coma follow. Death is due to renal acidosis and uræmia.

Polycythæmia and leucocytosis have been noted under Pathology.

Complications and Sequelæ.—Cardio vascular collapse, renal acidosis and uræmia, and toxæmia producing a typhoid state are common modes of death. Despite the frequency of uræmia, chronic nephritis rarely follows cholera. Complications also include broncho pneumonia, cholecystitis, parotitis and bed sores, and gangrene of the fingers, toes, ears, penis and scrotum have been recorded. Extreme local cyanosis may be mistaken for gangrene. Lack of lacrimal secretion may lead to conjunctivitis, corneal ulceration and sloughing of the cornea. Miscarriage and premature delivery are not infrequently caused by toxæmia, severe purging and cramps in the abdominal muscles.

Diagnosis.—When cholera is prevalent the only safe rule is to treat every case of diarrhœa as suspect until proved otherwise. Laboratory confirmation in all atypical cases should be sought.

During an epidemic little difficulty will arise, but in atypical and sporadic cases the diagnosis will largely be made on a positive stool culture. Outbreaks of food poisoning (cholera nostris) due to organisms of the *Salmonella* group may be differentiated by the history, the presence of bile in the stools and laboratory investigation. In mushroom poisoning the history is important and particles of the fungus may be identified in the vomitus or stools. Malaria, dysentery, early trichinosis and infection with *Gastrodiscus hominis* may occasionally produce acute gastro-intestinal features somewhat resembling cholera, laboratory investigations will clinch the diagnosis.

In poisoning by arsenic or mercury perchloride, vomiting generally predominates, the stools contain bile and sometimes blood, and there may be a marked metallic taste in the mouth.

Prognosis.—The mortality rate has varied in different epidemics from 30 to 80 per cent., being most fatal at the start. Modern treatment has reduced it to about 10 per cent. Over 90 per cent. of cases admitted with a blood pressure above 70 mm. recover. Young children, pregnant women, aged and debilitated people, alcoholics and chronic nephritics do badly. A severe and prolonged collapse stage, early anuria with uræmic symptoms and hyperpyrexia are unfavourable, but with modern treatment these can often be avoided. (See also Cholera Vaccination below.)

Treatment.—**PROPHYLACTIC.**—Personal prophylaxis is vital. Since cholera vibrios originate in the first instance from patients with cholera, isolation of the patients in fly-proofed wards, destruction of vomitus and excreta and sterilisation of soiled linen and clothing are most important measures. Milk must be boiled, water sterilised by boiling or chlorination and water and food adequately protected against pollution or contamination by flies. Cold meat, shell-fish, salads and raw fruit should be avoided, and the hands invariably well washed in antiseptic solution before eating. Drinking vessels and eating utensils should be cleaned in boiling water and dried by heat. Scrupulous care of the ice chest is essential. Houses should be fly-proofed where possible.

Cholera vaccination produces some degree of temporary immunity and is valuable in epidemics, provided virulent strains of vibrios have been used in the manufacture of the vaccine. The vaccine contains 10,000 million vibrios per ml.; the first dose is 0.5 ml, followed in 10 days' time by 1.0 ml. A "booster" dose of 1.0 ml. should be given at least every 6 months if continued protection be desired. In India, vaccines containing Inaba and Ogawa strains have yielded promising results. Immunity develops rapidly in from 4 to 10 days, and probably lasts 4 to 6 months. The mortality rate in the vaccinated remains high, but is reported to be about two-thirds that of the uninoculated. The value of cholera-phage as a causal prophylactic during an epidemic is undetermined, while its practical value in eliminating cholera vibrios from wells and cisterns is also uncertain.

CURATIVE.—Specific treatment resulting in the destruction of cholera vibrios and toxin remains a therapeutic ideal yet to be achieved. Intestinal antiseptics have failed. Sulphaguanidine has been favourably reported on when therapy is instituted early. No unanimity of opinion exists in regard to bacteriophage, which is administered orally at short intervals in a dose of 4 ml.

Apart from specific therapy, intravenous fluid medication and other measures have lowered the mortality from approximately 60 per cent. to 10 per cent. The principles involved are designed to: (1) rest the small intestine; (2) replace fluid and salts lost from the blood and (3) restore the acid-base equilibrium of the blood and tissue fluids. By so doing circulatory failure, hypochloræmia, renal acidosis and uræmia are prevented or combated.

gr 180, sodium chloride gr 90, water 1 pint) to counteract acidosis and uremia. During the *collapse stage* 1 pint of (b) is first given, and then the total quantity is estimated from the specific gravity of the blood is made up with Rogers hypertonic saline solution (a). Thus a specific gravity of 1063 to 1064 calls for 3 pints, and between 1065 to 1070 for 4 to 6 pints, the aim being to keep the figure below 1060. Injections are repeated as often as the specific gravity of the blood rises to or above 1063, or the blood pressure falls to 70 mm. Other solutions in use consist of isotonic saline, 5 per cent glucose, and a combined sodium chloride (1.4 per cent.) and sodium bicarbonate (1.5 to 3.0 per cent.) solution. The latter should be sterilised, either by filtration or by adding the sodium bicarbonate to the cooling salt solution after it has been sterilised by heat. It is not permissible to boil or autoclave sodium bicarbonate, as it is converted into the toxic carbonate.

Fluid should be administered intravenously, either intermittently or by continuous drip. The all important consideration is to restore and maintain blood volume by isotonic saline injections, and if for any reason isotonic saline cannot be injected into the veins it can be introduced intrasternally or subcutaneously.

The pulse and blood pressure probably serve as the best indicator of blood fluid requirements. A blood pressure below 70 mm, especially if there is associated cyanosis, restlessness, cramps and cold extremities, necessitates immediate transfusion with isotonic saline solution. The result is dramatic provided an adequate quantity of fluid be injected. Profound collapse is relieved, the skin becomes warmer, cyanosis disappears and the pulse and blood pressure are markedly improved. Injections should not be continued after the pulse and blood pressure have been restored. Cases of moderate severity require 2 litres of fluid every 6 or 8 hours for 1 or 2 days. As much as 31 pints in 4 days have been given in a severe case with resultant recovery. Special care should be taken (1) to avoid pyrogens in the water used for intravenous injection, (2) to see that the temperature of the injected fluid does not exceed 80° F (room temperature in the tropics), if the rectal temperature be elevated. The former precaution is necessary to prevent rigors, and the latter to prevent hyperpyrexia.

In the *reaction stage*, cold sponging is advisable whenever the temperature exceeds 103° F. Threatened uræmia is treated by alkaline drinks, injection of alkaline saline solutions per rectum and intravenously and dry cupping. Hot packs should not be used. Throughout this stage constant care is necessary, the chief dangers being hyperpyrexia and renal failure. In the treatment of hyperpyrexia cold sponging, an ice cap to the head and cold saline enemata may be tried, if these fail the patient should be placed on a rush mattress, and covered by a sheet over which water is sprinkled and on which a fan plays to cause evaporation. When the blood pressure fails to rise repeated adrenaline injections are said to be helpful.

As long as the renal function is depressed no increase in the diet should be made, and even after all acute symptoms have subsided the patient should be nursed in bed in the recumbent position for several days as fatal syncope may ensue if he sits up prematurely. When patients can tolerate food, the diet should at first be low in residue. Broths, jellies, white of eggs, underdone minced meat and farinaceous foods reinforced by vitamins are permitted.

N. HAMILTON FAIRLEY

maximum prevalence, occasionally in epidemic form, and also of its greatest mortality, chiefly owing to respiratory complications; but the disease may also occur in the warmer months. It is more prevalent in cities and industrial centres than in rural districts. In isolated communities the disease appears in epidemic form every 7 or 8 years with high mortality.

The heaviest incidence of whooping-cough is in the first 5 years of life, with a dangerous tendency to attack children under 2. Most susceptible children in intimate contact with it contract the disease. After 10 years of age attacks are comparatively uncommon, but are by no means unknown in adults even in those over 60, and, in some instances, over 80 years. The foetus *in utero* has been known to contract the infection from its mother, as also may the new-born child. More females than males are attacked. The frequency with which whooping-cough follows an attack of measles is noteworthy. It may occasionally be a precursor of laryngeal diphtheria.

Infectivity is greatest during the catarrhal and early paroxysmal stages; but its exact duration is variable. On rare occasions convalescents are said to have acted as carriers of the disease for several months.

The infection is usually conveyed by the mucous droplets expelled by the cough. Since the bacillus can resist drying for several weeks the infection may lurk in rooms and fomites, but this is uncommon. One attack almost invariably confers lifelong immunity.

BACTERIOLOGY.—The causative organism is *Hæmophilus pertussis* or the bacillus of Bordet and Gengou. This is a minute, slender rod closely allied to the bacilli of the influenza group. It is Gram-negative, and only flourishes on artificial media which contain blood or serum. It grows best at blood heat. The bacilli swarm in the larynx and on the ciliated epithelium of the air passages. Cultures are most easily obtained from the small pellets of viscid mucus which are expectorated at the end of a paroxysm of coughing. The blood of convalescents agglutinates the bacilli.

There are no post-mortem appearances which are distinctive, the changes found after death being due to complications. Of these, congestion of the air-passages, broncholitis and broncho-pneumonia are the most common, and are accompanied by general acute vesicular emphysema. The tracheo-bronchial lymph glands are usually soft and swollen.

The paroxysmal cough is attributed to hyperæsthesia of the respiratory mucous membrane with heightened excitability of the vagus nerve.

Symptoms.—The incubation period is difficult to fix with accuracy, owing to the insidious nature of the onset and the delayed appearance of the characteristic whoop, but it is probably 13 to 15 days. Extremes of 3 days and over 3 weeks have been claimed. During a typical attack three stages may be recognised—catarrhal, paroxysmal and convalescent.

The catarrhal stage lasts from 7 days to a fortnight—it is febrile, and resembles a somewhat severe respiratory catarrh; but the cough is more troublesome and bronchitic signs ill-marked. Recognition of the disease at this, the most infectious, stage is difficult unless the patient is known to have been exposed to the infection. Suggestive signs towards the end of the period are a tendency of the cough to assume a paroxysmal character, with greater severity at night, giving rise to suffusion of the face and occasionally to retching or vomiting. Bacteriological investigation by swab or cough plate and the detection of lymphocytosis will assist early diagnosis.

When the paroxysmal stage is reached the disease is unmistakable. Fever will usually have subsided; but the cough occurs in paroxysmal bouts, often spontaneous, but frequently the result of external stimuli, such as excitement, draughts, the ingestion of food or examination of the throat. Several paroxysms may occur in quick succession with longer or shorter intervening periods of freedom. The victim senses the cough impending, and may attempt to suppress it. If lying in bed a child will sit up, or if about may run to mother or nurse. A brief, deep inspiration is followed

by a rapid succession of short coughs, with open mouth and protruded tongue, which are continued until the chest is almost emptied of air. The face becomes congested or livid, the superficial veins are engorged, and the eyes fill with tears. The eyeballs protrude, the skin is bathed in sweat and suffocation appears imminent; but relief is suddenly afforded by relaxation of the laryngeal spasm and the occurrence of the whoop, a long-drawn creaking inspiration, which refills the lungs with air. The paroxysm then recurs, and may be repeated several times, leaving the child perspiring and exhausted. The bout often terminates with the discharge from the air-passages of a pellet of viscid, transparent mucus. A quantity of thin sticky secretion, which is sometimes blood-stained, may also flow from the mouth and nose. During the fits of coughing, which often last for 2 or 3 minutes, the child may faint or become convulsed and insensible. The contents of the stomach are often ejected, and the urine may be voided; in some instances incontinence of *fæces* occurs. Epistaxis is not uncommon in the more severe attacks. Subconjunctival hæmorrhage may occur, and petechiæ appear in the skin of the eyelids, root of the neck and other parts. Rarely the membrana tympani is ruptured, and blood escapes from the ear. In infants asphyxia may occur.

In the early paroxysmal stage the cough is only occasional, but its frequency soon increases, and in a case of moderate severity from 15 to 20 paroxysms occur in the 24 hours; in some attacks, however, they are much more numerous. They are characteristically most frequent and most severe at night.

Physical examination at this stage will still reveal signs of diffuse bronchitis; but this is now accompanied by a greater or less degree of acute emphysema and moderate abdominal distension is not uncommon. The forcible protrusion of the tongue over the lower incisor teeth often produces a shallow ulcer on the frænum linguae.

The duration of the paroxysmal stage is from 3 to 10 weeks, and after this convalescence begins. Whooping-cough is more prolonged in winter than in summer, and its duration is increased if complications ensue. After the whoop has ceased a fresh attack of respiratory catarrh may cause it to reappear; but this should not be regarded as a relapse, it does not render the patient again infectious.

A leucocytosis occurs even in the early catarrhal stage. The lymphocytes are increased out of proportion to the other cells; a typical count would be 15,000 to 25,000 white cells per c.mm. with from 50 to 70 per cent. lymphocytes. (At the age of 6 months, in health, the proportion of lymphocytes is 57 per cent. and at 2 years 53 per cent.) Myelocytes may also appear. The leucocytosis is increased after each paroxysm of coughing, and the highest counts are found during convulsions. The supervention of pneumonia increases the polymorphonuclear cells. In contrast with other infectious diseases the sedimentation rate in whooping-cough is usually retarded during the paroxysmal stage.

Course.—Attacks vary in their severity and duration. During outbreaks abortive attacks, only recognised by bacteriological methods, are said to be common. Mild infections may run their whole course in a week or two, and the whoop may be absent, whilst severe ones may last several months. As mentioned above, the number of paroxysms in 24 hours is some measure of the severity. The danger of supervention of complications is proportional to the severity of the attack.

When whooping-cough attacks the adult violent fits of coughing with a sense of impending suffocation but no whoop are common. Cyanosis, vomiting and even temporary attacks of unconsciousness may also supervene and subcutaneous ecchymoses appear. The legs may become oedematous and muscle rupture may ensue from the violence of the cough, which retains its paroxysmal character and nocturnal severity.

In infants, too, the whoop may be very imperfectly developed.

Complications.—These belong mainly to the paroxysmal stage—they are partly

mechanical and partly inflammatory in nature. The most serious are excessive vomiting, pulmonary complications and convulsions.

When the paroxysms of coughing are frequent and severe, excessive vomiting may lead to great emaciation and exhaustion. Diarrhœa and ileo-colitis may also occur, mainly in younger children, and during the summer months.

Pulmonary complications are frequent, and are more common during the winter. A mild bronchitis with general, but temporary, acute emphysema is the rule, and is of but little moment. Capillary bronchitis or broncho-pneumonia, with pulmonary collapse which at times is massive, are much more serious. They usually occur at the height of the paroxysmal stage, and are responsible for two-thirds of the deaths. In hospital practice their incidence is about 12 per cent. Interstitial emphysema of the lung may result from rupture of an air cell during coughing, but is only likely to be recognised when it overflows into the root of the neck and the connective tissue of the chest wall. Pneumothorax may complicate. Bronchiolectasis with pulmonary fibrosis is an occasional sequel of the disease. In the adult an asthmatic tendency may ensue.

A single convulsion may prove of little importance, but convulsive states in the form of *whooping-cough eclampsia* constitute a deadly but rare complication, which is seen chiefly in infants and young children. The convulsions occur after prolonged paroxysms of coughing or as a terminal event, but on occasions they may precede a paroxysm or occur in the intervals. Their cause is much disputed. It is tempting to associate them with the encephalitis of other infectious diseases. K. Neuburger attributed these and certain other nervous complications to air-embolisms which produces ischæmic central necroses. Vascular spasm has also been suggested as the cause. The cerebrospinal fluid may be under tension with a slight increase in mononuclear cells.

Coma or paralysis of variable duration and extent may follow convulsions. Transient or permanent hemiplegia, aphasia, paralysis of ocular muscles, or defects of sight, hearing and intelligence sometimes supervene; and bulbar paralysis and polyneuritis have been recorded.

The strain of the recurrent paroxysms of coughing may induce dilatation of the right ventricle of the heart, subconjunctival and even retinal hæmorrhages and detachment, cutaneous petechiæ, epistaxis, bleeding from the mouth or ears, hæmoptysis and hæmorrhage on the surface or less commonly in the substance of the brain. Other results are the appearance of hæmiz and prolapse of the rectum.

True nephritis is rare, but transient albuminuria may appear. Glycosuria is occasionally found.

An inflamed condition of the naso-pharynx may persist after the cough has subsided, and no other disease except measles has such a bad reputation as a forerunner of tuberculosis.

Diagnosis.—In the absence of known exposure to infection, diagnosis may be impossible until the whoop is heard; but the significance of a refractory and paroxysmal cough, worse at night and terminating in retching or vomiting, should not be overlooked. The disproportion between the violence of the cough and the accompanying physical signs in the chest is also noteworthy. When broncho-pneumonia does supervene the whoop may cease. In infants the cough may be paroxysmal and asphyxiating, but the whoop not developed; in such cases, as also in adults when the whoop is absent, the diagnosis may be cleared up bacteriologically or by the occurrence of infection in contacts.

Bacteriological diagnosis may be effected by post-nasal or laryngeal swabbing or, better, by receiving the invisible droplets ejected during a bout of coughing on a modified Bordet-Gengou culture medium in a Petri dish, held 6 in. in front of the mouth. The medium consists of defibrinated blood-agar, human blood being used by preference. The growth should be recognisable in 48 to 72 hours as small glistening

colonies of minute ovoid, Gram negative rods, frequently paired. More than one exposure may be necessary especially in infants. A negative result does not necessarily exclude whooping cough. The bacteriological method may also be applied to determine the cessation of infectivity, three negative results on successive days being accepted as satisfactory.

The spasmodic cough of bronchial gland irritation, of adenoids, or that induced by a foreign body in a bronchus, is apt to be paroxysmal, but the whoop is wanting. The same observation applies to the obstinately recurrent coughs of influenza and bronchiolectasis. In children, laryngeal inflammation of catarrhal or of syphilitic origin may induce paroxysms of cough and laryngeal spasms, but the tone of the cough at once indicates its laryngeal origin. Conversely, whooping cough in its early stages, if accompanied by an unusual amount of laryngeal catarrh, may be confused with the laryngitis of measles or of diphtheria. In adults the laryngeal crises of tabes or fits of coughing induced by thoracic aneurysms intra thoracic growths or local laryngeal lesions occasionally suggest whooping-cough.

In the catarrhal stage the malaise, cough, pyrexia and slight fullness of the abdomen with perhaps some irregularity of the bowels, may arouse unfounded suspicions of early general tuberculosis.

The leucocytosis of whooping cough, which is considerable in the early stages, may prove of assistance in the diagnosis of the disease, especially if combined with sputa teeming with slender Gram negative organisms like influenza bacilli and a normal erythrocyte sedimentation rate. The count should, of course, be compared with that normal for the child's age (see p. 752).

The presence of the sublingual ulcer is only to be expected after the incisors have appeared. Occasionally it is seen in other conditions of persistent cough.

An authentic history of a previous attack puts whooping-cough for all practical purposes out of court, second attacks being excessively rare.

Prognosis—Whooping cough is a much more serious malady among the families of the poor, and in those suffering from malnutrition, rickets, tuberculosis or a pre disposition to chest troubles than it is to healthy, well fed children. Apart from this age constitutes the most important prognostic factor. Infants and children under 3 years of age suffer a considerable mortality, which for the first 12 months of life may be as high as 25 per cent. The mortality decreases rapidly after the third year, and after 10 years of age is insignificant. Pulmonary complications cause most of the deaths, occurring chiefly in the winter months. In the summer, *ileo colitis* may come into prominence.

Convulsions especially if repeated are of grave omen. Death at times occurs suddenly from asphyxia due to sustained laryngeal spasm or from heart failure, intracranial haemorrhage or, it is suggested air embolism. When tuberculous lesions are present these may be stirred into activity by the infection, and especial care is necessary.

A cautious prognosis should be given with regard to paralytic sequels, since in a number of cases these prove permanent.

Treatment—Isolation should be enforced and trustworthy attendants provided. Free ventilation with abundance of fresh air gives better results than confinement in a close room and the inhalation of medicated vapours. In the absence of fever, older patients may be allowed up and out as much as possible provided isolation can be maintained. In suitable weather continuous open air treatment may be adopted even for those patients who are confined to their beds. It is especially valuable in broncho pneumonia. A light binder should support the abdomen and the clothing be loose and not too heavy. The diet must be light and digestible. Dry solid food often induces coughing. Milk and cream form a valuable basis. When vomiting is persistent it is a good rule to administer food in small quantities shortly after the paroxysms of coughing. Overloading the stomach may aggravate the cough. A

diet of milk or whey may be considered in some instances. Orange juice with glucose should be given freely

The bacillus is insensitive to penicillin, but both this and sulphonamides may be of use in some secondary complications. Chloramphenicol gives satisfactory results in some cases, but a number of instances of aplastic anaemia have arisen from its use in pertussis, and its continued employment is unjustifiable. Some strains of the organism are sensitive to streptomycin. Chlorotetracycline has been effective in other cases. Two other closely related antibiotics, aerosporin and polymyxin have also been used with some successful results. During the catarrhal stage simple expectorant mixtures are sufficient, and later the paroxysms may be modified by such sedatives as belladonna, phenazone, bromoform, phenobarbitone, paregoric, codeine and heroin, all of which have their advocates. Tincture of belladonna in increasing doses (2 or 3 minims 4-hourly cautiously increased until the pupils are widely dilated) and phenazone are the most generally useful; the latter may be given to a child in doses of gr 1 or 2 with small doses of potassium iodide and expectorants every 4 to 6 hours. Ephedrine (one twelfth of a grain in infancy to one-half grain for a child of 5 years in a simple linctus) is also a good antispasmodic given three times a day. Remarkable amelioration of the cough and vomiting may be effected by the use of heavy doses of sodium bicarbonate, the urine being made and kept fully alkaline. Vaccine treatment with the Bordet-Gengou bacillus is still on its trial. Its prophylactic is greater than its curative value. Smooth, recent, virulent strains are essential. Spaced at monthly intervals three injections are given, starting with 5000 million organisms and rising to 10,000 million. Horse, rabbit and hyper-immune human antisera have been used, there is some evidence that the last is of value if used early in infants under 1 year of age, but the other two do not appear to affect the course of the disease. Attention should be paid to the condition of the nose and throat, and adenoids removed as soon as possible in convalescence, since they tend to maintain the cough. As after-treatment, tonics and a change to the sea side are advisable.

Complications should be treated on general lines. Obstinate vomiting needs careful feeding, and phenobarbitone one-sixth to one-quarter grain three times a day, or intramuscular injections of soluble phenobarbitone. Gastric lavage with 0.6 per cent solution of sodium bicarbonate may help. Asphyxial attacks are treated by pushing forward the lower jaw and applying artificial respiration. The mouth and pharynx should be cleared of mucus. Inhalation of O_2 and CO_2 is said to be of good effect. Intubation has been practised in some very severe cases. Convulsions call for the mustard bath or hot pack, with an enema of paraldehyde (1 to 1½ drachms) in olive oil. A whiff of chloroform may give relief, and sometimes lumbar puncture with free escape of cerebrospinal fluid is effective. Broncho-pneumonia should be treated with sulphonamides or the appropriate antibiotic. Atelectasis requires similar treatment, followed by stimulant expectorants, breathing exercises and postural drainage.

The injection of the serum of convalescents, on the same lines as in measles and in similar doses (qv), has been advocated as a prophylactic but has proved disappointing.

Although the infectivity of the paroxysmal stage, especially of its latter part, is problematical, patients should be isolated for 5 weeks from the commencement of the whoop, provided the paroxysmal cough and whoop have ceased for a fortnight, or, better, until the infecting organism has disappeared, which may occur after 3 weeks of illness, or a week or two later. The quarantine period for non immune contacts is 21 days. Disinfection of rooms and clothing is desirable.

CHANCROID

Synonyms —Soft Chancre, "Ulcus Molle" and Ducrey's Infection

Definition —An acute localised specific infectious disease due to the entrance of a micro organism (*Hæmophilus ducreyi*) into the tissues of skin or mucous membrane

Ætiology.—The infection is nearly always transmitted during sexual intercourse. Accidental infection is rare. The disease is widespread throughout the world but the incidence is highest in tropical countries. In this country it is not common and is limited, for the most part, to seaports. It is found much more often in men than in women. The figures of incidence in the Report of the Chief Medical Officer of the Ministry of Health show 389 new cases in males and 14 new cases in females in England and Wales during 1952. The total number, 403 cases, compares with 19,659 cases of gonorrhœa, the most prevalent venereal disease. It is generally regarded as a disease of the highly promiscuous and the unhygienic. Symptomless carriers are known to exist.

Pathology.—The organism, *H. ducreyi* or streptobacillus of Ducrey, is a small, slender Gram-negative bacillus which is often seen in chain formation but may be found singly or in groups. It may be difficult to find in smears from the open sores because of secondary infection. It is a fastidious organism and usually, difficult to grow in culture, although in expert hands media containing defibrinated human or rabbit's blood have given good results. The microscopic picture of chancroid is said to be distinctive and biopsy to be a useful method of diagnosis.

Symptoms and Signs.—The incubation period is short, namely, 3 to 5 days in most cases. Occasionally it may be as short as 24 hours. At the site of inoculation, which is nearly always on the genitalia, there first appears a small red painful papule or pustule which quickly breaks down to form an ulcer. The ulcer is usually very painful and extends quite quickly by local tissue spread. It may also ulcerate deeply and be very destructive. It tends to be irregular in outline, with undermined edges and a narrow zone of bright red erythema at the spreading margin. Surrounding tissue may show an erythematous blush. The floor of the ulcer is covered with yellowish slough which exudes pus. The granulations bleed freely on manipulation. The base of the sore is not indurated. Occasionally the granulations become exuberant and elevated above the surrounding surface, so called "ulcus molle elevatum". Multiple sores are more common than single sores, in contrast to primary syphilis from which the diagnosis must be made. Auto inoculation is common. In many cases the regional inguinal lymphatic glands become involved, after periods varying from 2 days up to 3 weeks from the appearance of the sore. The adenitis is very painful and develops quickly. The skin over the swelling is reddened, the glands become matted together and soon suppurate with the formation of a large single abscess, the "inflammatory bubo". This is likely to break down on the surface of the skin to form a large chancroidal ulcer in the groin. Painful lymphangitis may also occur. Other complications which have been described include hæmorrhage from the ulcer, urethral stricture, urethral fistula, phimosis and spreading gangrene.

Diagnosis.—The diagnosis is frequently made on clinical grounds, but it is important to try to find the organism by smear or by culture. An intradermal test, the so called "Ito-Reenstierna" test, is performed by injecting a quantity (0.25 ml.) of a saline suspension of killed *H. ducreyi* into the skin. The commercial vaccine, Dmelcos, which is made up into concentration of 450 millions of organisms to the millilitre, is usually used. A positive result may be found after 24 to 48 hours and takes the form of an inflammatory papule of diameter 0.5 cm. or larger, surrounded by erythema of the skin. A positive test is not to be expected until 7 days or more after the appearance of the sore. Once the sensitivity has developed a positive test will be found over a period of years and perhaps always. If the patient gives a history

of an earlier genital sore, a positive result should therefore be interpreted with reserve

Treatment—Local treatment is likely to be ineffective although the application of powdered iodoform is probably of some value. The penetrating smell of this preparation is however, unpleasant to many patients. The sulphonamide drugs are effective remedies for the condition, but they usually have to be given for periods which entail risk of the effects of sensitisation, and they are not always successful in producing cure. Common practice is to give sulphathiazole, or equivalent, in the dosage of 5 g daily for 10 to 14 days. There is some evidence that *H. ducreyi* is sensitive to penicillin *in vitro* but *in vivo* the drug appears to be of no value. On the other hand, intramuscular injections of streptomycin have an excellent effect. Standard dosage has been 1 or 2 g daily for about 5 days, although in some cases administration has been continued for 2 weeks or more. Both chloramphenicol and chlortetracycline given in the dosage of 0.5 g four times daily until healing is complete have been shown to be effective in the treatment of chancroid. Oxytetracycline has also been used successfully, employing the same dosage for a period of 5 days. Most of the cases respond to sulphonamides or streptomycin and these are the remedies of choice because they will not suppress the early signs of syphilis if the patient is incubating that disease.

When treatment is finished and the lesions have healed it is customary to keep the patient under observation for 3 months and to perform blood serological tests at monthly intervals because of the possibility that syphilis may have been contracted at the same time and that the primary lesion, with its longer incubation period, may have appeared late and been obscured.

AMBROSE KING

BARTONELLOSIS

Two clinical forms of Bartonellosis are now recognised namely, (1) Oroya fever in which there is a generalised infection with *Bartonella bacilliformis*, and (2) Verruga peruviana in which there are local lesions in the skin.

OROYA FEVER

Synonyms—La Maladie de Carrion, Carrion's Disease, Generalised Bartonellosis.

Definition—An acute infectious disease caused by *Bartonella bacilliformis* characterised by irregular remittent fever, headache, tenderness over the bones and a severe anaemia of megalocytic type. Fatalities are frequent.

Ætiology—Oroya fever is limited to valleys on the western slopes of the Peruvian Andes between 1800 and 9000 ft. Both sexes are susceptible and children may be attacked. Carrion (1885) inoculated himself from a verruga nodule and died of Oroya fever a month later. Barton (1909) found rod like organisms in the red cells in this disease, they were also numerous in the endothelial cells of the lymphatic glands, liver and spleen. Noguchi (1926) cultured the organism and subsequently experimentally infected monkeys the susceptible animals developing a condition like Oroya fever, the most resistant ones lesions of verruga peruviana only. The disease is most prevalent from January to April when insect life is most plentiful. Transmission is probably by sand flies of the species *Phlebotomus noguchi* and *P. verrucarum*.

Pathology—The skin is yellow, the lymphatic glands liver and spleen are enlarged and the long bones filled with red hyperplastic and megaloblastic marrow. The heart shows fatty degeneration, the liver zonal necrosis while endothelial cell hyperplasia is common. Petechial hæmorrhages occur in the skin and serous sacs.

The intra-cellular pigment described in sections of the spleen, liver, etc., arises from the blood destruction associated with acute bartonella infections

Symptoms—The incubation period is about 3 weeks, the onset being fairly rapid, with malaise and headache. Irregular remittent fever somewhat similar to paratyphoid, pains in the joints and tenderness over the long bones are characteristic, while the spleen and lymph glands may be enlarged. Grave anaemia of hemolytic megalocytic type rapidly develops, in the severe cases the red cells falling as low as 1,000 000 per c mm. The colour index often exceeds 1.0, and polychromatophilia, poikilocytosis, normoblasts, erythroblasts and even megaloblasts are evident in blood smears. The indirect van den Bergh reaction shows hyperbilirubinæmia. Unlike pernicious anaemia it presents a marked leucocytosis with a shift to the left, myelocytes and meta myelocytes being present, lymphoblasts, Turk cells and the Rieder type of lymphocyte are also common (Monge and Weiss). Oedema of the legs, cardiac murmurs and retinal hæmorrhages may occur, while hæmorrhagic manifestations of the skin and gums, and coma with subnormal temperature are met with in severe cases. The acute stage of the illness lasts some 2 weeks, and may either terminate fatally or pass on into the eruptive stage with chilblain like nodules, *ie* verruga peruviana.

Diagnosis—The rod shaped bacilli are only demonstrable in the blood smears in severe infections, and Noguchi preferred culturing *B. bacilliformis* for this reason. The limited geographical distribution and the rapid onset of a febrile megalocytic anaemia are important features in diagnosis, but malaria, paratyphoid, rheumatic fever and tuberculosis may need to be differentiated.

Prognosis—A great variation in the intensity of the infection in different patients is noted. Mild cases recover, but in well established cases of Oroya fever the mortality rate is from 30 to 40 per cent.

Treatment—**PROPHYLACTIC**—Sand fly bites should be avoided by sleeping under netting having a 22 to the inch mesh, or ordinary mosquito netting which has been impregnated with DDT. Other measures similar to those used to prevent phlebotomus fever (p. 189) should be instituted.

Treatment is symptomatic, no specific remedy being available.

VERRUGA PERUVIANA

Synonym—Localised Bartonellosis

Definition—This is the eruptive stage of Oroya fever in which host resistance is high, miliary and nodular lesions may result which show a marked tendency to ulceration and hæmorrhage.

Ætiology—The disease may be transmitted by local inoculation from monkey to monkey, and Noguchi has successfully cultured *B. bacilliformis* from the local lesions. Only specially susceptible animals show the systemic manifestations associated with Oroya fever.

Pathology—The pathological lesion is a very vascular, infective granuloma showing a marked tendency to ulceration and hæmorrhage. The endothelial lining of both lymphatics and capillaries proliferates. Plasma cells and fibroblasts appear in an oedematous, delicate reticulum containing numerous blood vessels around which angioblasts undergoing mitosis may accumulate, the late appearances may simulate fibrosarcoma.

Symptoms—The incubation period varies from 2 to 5 weeks, when rheumatic like pains develop in the limbs and joints associated with moderate fever which generally subsides within a few days. Subsequently an eruption of tubercles and nodules occurs. The miliary type of lesion commences as a red macule which gradually develops into a flat or pedunculated wart like structure about the size of a small pea, the lesions occur most frequently on the face and extensor surfaces of the arms.

and legs, but similar ones may involve the mucous membranes of the eyes, nose, pharynx and larynx, giving rise to cough, hoarseness, epistaxis and even sudden death. The *nodular type* of lesion may attain the size of a chestnut; these tumours often ulcerate, forming large, bleeding, fungating masses situated in the flexures of the joints and appearing in successive crops. Little difficulty is experienced in diagnosis and fatal results are rare, though the disease may last 2 to 3 months.

Treatment.—When the nodules ulcerate they should be dressed with antiseptics, and if they undergo necrosis or hæmorrhage severely they may be excised.

N. HAMILTON FAIRLEY.

PNEUMOCOCCUS INFECTIONS

LOBAR PNEUMONIA (see p. 1048).

BRONCHIO-PNEUMONIA (see p. 1058).

BOTULISM (see p. 123).

B. DISEASES CERTAINLY, OR ALMOST CERTAINLY, DUE TO FILTRABLE VIRUSES

INTRODUCTION

A number of human diseases, examples of which are small-pox, rabies, yellow fever, chicken-pox, measles and epidemic poliomyelitis, are now known to be caused by ultra-microscopic viruses, and, arguing from analogy, encephalitis letbargica is thought to belong to the group, though proof is still lacking.

As a rule, these viruses measure less than 250 $m\mu$, and some of them measure much less. Particles less than 250 $m\mu$ cannot be resolved by ordinary microscopes, though Barnard, by the use of a short-wave ultra-violet light and lens systems of quartz has resolved objects as minute as 75 $m\mu$. Of recent years the physical characteristics of many viruses have been revealed and studied by means of the electron microscope. Great diversity of size occurs amongst the viruses. With few exceptions, however, the viruses are ultra-microscopic, and will pass through filters that fail to pass the pathogenic bacteria.

Though differing much in size and effects, most of the viruses have characteristics in common. Many of the diseases caused by filtrable viruses in man and animals are highly infectious, very minute doses of virus causing infection—an infection that spreads with great rapidity. Many of the virus diseases produce special intracellular bodies, termed inclusion bodies. These may be restricted to one particular tissue, or may be found in various tissues. They may occur in the cytoplasm or nuclei of cells, or in both, and vary greatly in size. In some diseases the diagnosis can be made histologically by the recognition of these bodies, e.g. the Negri bodies in rabies. The fact that the inclusion bodies have been seen to develop *in vitro* in tissue-cultures suggests that the filtrable viruses are intracellular parasites, in which respect they differ from the majority of bacteria.

Some of the virus diseases, such as yellow fever, dengue and papataci fever, are insect-borne.

No virus has been cultivated *in vitro* in the absence of growing cells, though many can be propagated in tissue cultures, and on account of this exception, many, if not the majority of workers, hold the opinion that pleuro-pneumonia is not a virus disease. Generally speaking, therefore, viruses can only be propagated by animal passage.

Most of the viruses produce an active immunity which is very lasting, and in

some of the diseases immune serum confers passive immunity. In measles the injection of immune serum will produce such a degree of passive immunity as to prevent an attack of measles in a contact, but such immunity is not lasting. If given about 6 days after contact, a modified attack of measles of very attenuated type will occur, subsequent to which permanent immunity ensues. Work published by the Rockefeller Institute shows that fully inactivated yellow fever virus will not confer immunity. Inactivated distemper virus will, however, immunise, and is indeed used as a preliminary measure in the prophylaxis of distemper, and inactivated virus also confers immunity in cattle plague, fowl plague, rabies, influenza (in mice), herpes and some other animal diseases.

Most of the filtrable viruses are resistant to glycerine, especially at low temperature, and remain unaltered for long periods in 50 per cent thereof at 4° C, whereas the lethal effect of glycerin on bacteria generally is well known.

Complement fixation reactions between virus and antibody have been shown in many virus infections, and flocculation has been shown in the case of variola virus. Ledingham has shown that homogeneous suspensions of the elementary corpuscle from vaccinia and fowl-pox are agglutinated by the sera of convalescent animals, while normal serum has not this effect.

The following list comprises some of the human virus diseases under two headings

1 *Certain*

Small pox	Herpes Febrilis
Chicken pox	Herpes Zoster
Mumps	Infectious Warts
Yellow Fever	Acute Anterior Poliomyelitis
Dengue Fever	Psittacosis
Phlebotomus Fever	Rabies
Rift Valley Fever	Encephalitis (St. Louis Type)
Lymphogranuloma Inguinale	Influenza
Common Cold	Measles

2 *Almost Certain*

Encephalitis Lethargica	Molluscum Contagiosum
Primary Atypical Pneumonia	Rubella
Epidemic Infective Hepatitis	Homologous Serum Hepatitis

THE COMMON COLD

Synonyms —Acute Coryza, Cold in the Head

Definition —An inflammatory process affecting the upper respiratory tract in which the air sinuses and tubes in connection therewith may also be involved.

Ætiology —Colds are very common in the damp variable weather of the autumn, winter and spring in temperate climates. Susceptibility to infection tends to diminish with age, yet shows great variation amongst different individuals and even in the same individual under different conditions. Both sporadic and epidemic forms are met with, and infection may spread through a community with great rapidity. Amongst important predisposing causes are frequent changes of atmosphere, as by entering and leaving hot, stuffy, ill ventilated, crowded rooms, the presence of a focus of chronic infection in the upper respiratory tract, e.g. adenoids, infected tonsils and chronic cranial sinusitis, structural anomalies which interfere with free ventilation of the nose, e.g. deflected septum and polyp, and chronic irritation of the mucosa

by smoke, dust or chemicals in sprays, etc. Very little is known of the exact pathogenesis, but there would appear to be at least two factors. A filtrable virus is primarily responsible, aided by other organisms which set up a secondary infection, either severally or together. The infective agent is air-borne, and spread is most likely by droplets expelled from the nose and naso-pharynx by sneezing, speaking, coughing etc. The portal of entry is the nasal or pharyngeal mucosa and, possibly, the conjunctival sac, infection develops locally via the submucous lymphatics to neighbouring areas, all or one of which may bear the brunt of the inflammation, the resulting clinical picture being an acute rhinitis, sinusitis, pharyngitis, laryngitis or tracheitis. The secondary infection may be by organisms already present as normal inhabitants on the inflamed mucosa, e.g. pneumococcus, *Streptococcus viridans* or *Neisseria catarrhalis*; or pathogenic bacteria generally conveyed by droplet, e.g. *Haemophilus influenzae*, *Streptococcus pyogenes*, *Staphylococcus pyogenes*. It is impossible to be dogmatic as to which signs and symptoms are consequent on the primary or the secondary infection respectively, it may be that variations in symptoms and the degree of the accompanying toxæmia in different individuals in the same epidemic are due to variations in the secondary infection. It has been postulated that an allergic response to the virus may be responsible for the initial symptoms. Local infection induces vasodilatation and œdema in the spongy submucous tissues and engorgement of the mucosa, with outpouring of mucoid secretion, which soon becomes mucopurulent in character. The swelling may cause obstruction to the outlet of an air cell, particularly in the ethmoid or sphenoid, or to the duct of the frontal sinus, absorption of air behind such an obstruction may be responsible for a "vacuum headache", or if the Eustachian tube is involved to deafness and vertigo, when an air sinus is implicated in the inflammatory process and its opening is obstructed, local pain and "distension headache" are prone to follow.

Clinical Features.—The incubation period varies considerably but is usually between 12 and 48 hours, it would appear to be shortened by chilling of the body or exposure to wet. The first symptom is often a stuffiness in the nose, which is soon accompanied by a prickling sensation and sneezing, a profuse discharge, at first mucoid but which within 12 hours becomes mucopurulent, may lead to excoriation of the anterior nares. Taste and smell are impaired. Pharyngitis and tonsillitis are common, and there may be some follicular exudate on the tonsils. If the inflammation spreads to the larynx, the voice becomes hoarse, and a tracheitis will induce a painful irritating cough which may be paroxysmal, especially at night, and retrosternal soreness. Symptoms are confined in the main to the respiratory tract. Constitutional disturbance is usually slight, though in some epidemics the temperature may reach 102° F. for 48 hours. In such cases pain in the back and limbs and a sense of exhaustion may be experienced. The catarrh slowly subsides, and the patient is usually free from symptoms in from 4 to 7 days. Immunity is shortlived.

Complications and Sequelæ.—When these arise, they are most times consequent on the secondary infection. Some suffusion of the conjunctivæ is common. Herpes around the nostrils and on the lips may be extensive during the acute stage. Suppuration in the accessory sinuses or an acute otitis media may occur. Bronchitis, especially in those patients liable to that disease, may flare up and persist for a long time. Broncho-pneumonia is the most serious complication, and not a few cases of pulmonary tuberculosis follow a "neglected cold". Routine radiological examination of the lungs in patients suffering from acute coryza shows a proportion to have an area, or areas, of diminished translucency resembling those seen in primary atypical pneumonia (see p. 1056). As a rule there are no physical signs of pulmonary consolidation and the shadows completely disappear, perhaps they represent a form of "virus pneumonia", although inhalation of infected material from the upper respiratory tract seems a more probable explanation.

Treatment.—**PROPHYLACTIC.**—The avoidance of infection in the community is

well-nigh impossible, but much may be done by efficient ventilation and fresh air. When knowingly exposed to infection, it is a good rule to keep the mouth shut as far as possible, and on leaving some individuals have faith in taking a pinch of snuff into each nostril. Stock anti-catarth vaccine possibly has a prophylactic value in some seasons; though the results of inoculation may appear encouraging through one winter, they may be disappointing the next, or *vice versa*. It can be expected to do nothing more than discourage secondary infection.

GENERAL.—Though isolation is, in theory, admirable both for the protection of the patient and for limiting the spread of the disease, in practice it can be enforced but seldom. If there is much constitutional disturbance, if the patient suffers from the frailty of old age, or active pulmonary disease, or diabetes mellitus, or subacute nephritis, or heart failure, the common cold must be taken seriously and the patient confined to bed until free from symptoms for 48 hours.

Treatment is entirely symptomatic. The antihistamine drugs are effective in reducing the discomfort of a cold in occasional patients, provided administration is started within an hour of onset. Their general efficacy has not been established, but in those particularly susceptible, promethazine hydrochloride (Phenergan) 25 mg, three times daily is worth a trial. In the early stage stuffiness of the nose and throat may be relieved by inhalation for 10 minutes from a jug containing boiling water, 1 pint and cold water $\frac{1}{2}$ pint (or a pint of boiling water allowed to stand for 7 minutes), r. benzoini co., min. 60, and menthol gr. 2. This should not be done just before the patient goes out of doors. A solution of 2 per cent. silver nitrate or colloidal silver may be used as a spray. Amphetamine and ephedrine may give temporary relief to symptoms by shrinking the congested nasal mucosa; they should not be used to excess. Diaphoresis is encouraged by aspirin, Dover's powder and a hot drink at bedtime. Drugs of the sulphonamide group should not be administered as a routine; only when a pyogenic complication develops should the appropriate drug be given, and in full dose.

MEASLES

Synonym.—Morbilli.

Definition.—A highly infectious specific fever, characterised by catarrh of the respiratory passages, the presence of Koplik's spots on the buccal and other mucous membranes, a distinctive widespread papular eruption on the skin and a special liability to otitis and to pulmonary complications.

Ætiology.—Measles is of world-wide distribution. Both sexes are equally liable. It is extremely infectious, and there is little evidence that natural immunity ever occurs, but a temporary active immunity without an overt attack may be acquired during epidemics. When introduced among unprotected communities it spreads with appalling rapidity to persons of all ages, and causes many deaths. More than half the attacks of measles occur in the first 5 years of life, and seven-eighths of all cases occur in children under 10. There is a temporary passive immunity of the new-born child, possibly due to transmitted maternal immunity, which gradually wanes after the first 3 months, and infants under 6 months rarely take the disease. Early incidence is most pronounced in poor and crowded communities; among the middle classes it is delayed to school age or later.

When measles occurs in a pregnant woman abortion or premature delivery often results, and the infant may also exhibit the rash, usually in the same stage as the mother (*Congenital Measles*). Congenital defects similar to those caused by rubella (*q.v.*) are known to have occurred, but less commonly. The disease is endemic in large cities, and cases are numerous from October to March. Epidemics recur with remarkable constancy every 2 years, and every tenth year an especial incidence is said to be noticeable.

The virus resides in the secretions of the respiratory tract and direct infection is the rule, very intimate contact is not essential. Infectivity may be present 5 days before the appearance of the rash, possibly longer, and then rapidly declines. Only on rare occasions do intermediaries convey the infection, and rooms and fomites do not retain it for more than a short period. There is no evidence incriminating water, milk or other articles of food.

Pathology.—The causal agent is a filtrable virus. The disease has been reproduced in man and monkeys by inoculation with blood, bronchial secretions or tears. The infective agent can be cultivated in chick embryos. The primary morbid change is a generalised hyperplasia of lymphoid tissue in which many cells resembling histiocytes appear. In fatal cases the most striking visceral change is broncho-pneumonia. Secondary infections chiefly with hæmolytic streptococci are common. Catarrhal or ulcerative laryngitis may be found. The bronchial glands are inflamed and the lymphoid aggregations of the small intestine may be very conspicuous. Measles is prone to activate pre-existing tuberculous lesions.

Symptoms.—**Incubation.**—The rash appears on the fourteenth day of infection, sometimes a day earlier or a day later, but it may be delayed in patients who have been injected with the serum of convalescents. This interval is more constant than that which elapses between infection and the first catarrhal symptoms. Reckoning to the onset of fever and catarrh 9 or 10 days usually pass. In some cases the incubation period is slightly febrile and a transitory feverish catarrh with fleeting rash has occurred even a few hours after exposure to infection (Goodall's *illness of infection*). A polynuclear leucocytosis is characteristic of the incubation stage. Slight enlargement of the cervical, inguinal, axillary and other glands may herald the eruption. Koplik's spots on the buccal mucosa may precede the rash by 2 or 3, sometimes by 5, days. Prodromal rashes are not uncommon; a precocious macular eruption is the commonest, but a punctate scarlatiniform erythema is the most important, since it simulates scarlet fever. It is apt to appear on the second day of invasion. An urticarial rash may also occur.

Invasion.—This is signalled by catarrh of the respiratory tract, fever and the outbreak in the mouth of Koplik's spots. It culminates in the appearance of the skin eruption. Sneezing, irritating cough, watery eyes and conjunctival injection are the early signs. There is chilliness, and the temperature may reach 103° F. by the end of the first day. Photophobia and sharp diarrhoea may occur. In the early stage of invasion slight blotchiness of the skin about the mouth and nose may be evident. The cutaneous rash usually appears on the fourth day, and a deceptive remission of symptoms and fall of temperature sometimes occur just before its outbreak. In some instances laryngeal symptoms are marked during the invasive stage, and give rise to suspicion of diphtheria; exceptionally, catarrh is insignificant, and an attack of severe simple tonsillitis is simulated.

Koplik's spots are of great importance in the early diagnosis, since they are usually recognisable some 72 hours before the rash, with the appearance of which they rapidly disappear. They are minute superficial specks of a bluish-white tinge, and show a tendency to aggregate into small clusters or granular patches. Their common site is on the inner aspects of the cheeks, opposite the line of apposition of the molar teeth; but they may be more widely scattered over the buccal mucous membrane, on the inner surfaces of the lips and on the conjunctivæ. There is evidence that they also occur on the mucosa of the colon. Sometimes they are surrounded by bright red areolæ. In addition, the mucous membrane of the mouth becomes congested and dusky, and a decided blotchy exanthema may here precede the cutaneous eruption.

Period of eruption.—With the approach of the rash the symptoms become aggravated. The temperature rises sharply, it may be to 104° or 105° F. The hurried respiration and slight cyanosis may suggest broncho-pneumonia. Diarrhoea may persist, and sometimes urinary irritation is noticeable. The nasal and conjunctival

discharges become more purulent. The eruption makes its first appearance about the brows, behind and below the ears, and in the circumoral region. Rarely, it appears first on other parts, such as the buttocks, thighs or wrists. It spreads rapidly, sometimes after a short hesitation, over the face, neck, trunk and extremities, and is usually fully out on the fifth or sixth day of the attack. Small brownish macules are the first elements, but they soon become papular, and show a tendency to fuse into groups with irregular sinuous outlines. Profuse eruptions may become confluent on the face, neck, back and extensor aspects of the limbs. Petechial hæmorrhages in the rash are not uncommon. The skin is usually moist and exhales a peculiar musty smell. Rarely, it is hot and dry. Itching or burning sensations may accompany the rash.

The eruption fades in the order of its appearance, and usually disappears in the course of 2 or 3 days, but brownish staining may persist for some time, particularly on the back. A fine branny desquamation speedily follows. At its first appearance, the rash may fail for a time to spread; retrocession is also sometimes observed. A badly developed and retarded rash is characteristic of some severe attacks, and in asphyxial states the rash may be cyanotic. As the rash develops, the temperature continues to rise, reaching its maximum with the climax of the eruption in from 24 to 48 hours. When the rash begins to fade, the temperature falls more or less abruptly by a crisis which is rather prolonged.

The pulse-rate is increased in proportion to the fever, but the respiration is disproportionately rapid. The catarrhal symptoms also reach their greatest intensity at the height of the eruption. Headache, slight delirium, insomnia and a feeling of intense wretchedness are characteristic of this period. The throat may be sore, the buccal mucous membrane show an intense catarrh and the glands at the angle of the jaw become tender. The tongue at first is heavily coated, but before long red papillæ are evident, and when peeling is complete a clean, red papillated tongue, very like that of scarlet fever, may often be seen. With the crisis rapid amelioration of all symptoms should occur.

The blood now shows a leucopenia with a high percentage of large lymphocytes. All complications induce a polynuclear leucocytosis.

The urine presents the ordinary febrile characters. Transitory albuminuria may occur. Ehrlich's diazo-reaction is nearly always present, and is most marked when the temperature begins to fall. An acetone reaction is obtained in most cases.

VARIETIES—Attacks may be mild or severe. Some of the mildest attacks are abortive, the rash failing to appear, and only Koplik's spots giving a clue to the disease. Such attacks may also be seen after serum prophylaxis. Severe attacks are classified as toxic, pulmonary and hæmorrhagic. The *toxic type* includes those cases in which the patient may succumb during the eruptive period without evident complication. Ill-defined rashes, high fever, muscular tremor, delirium, dyspnœa and circulatory failure are characteristic features. In the *pulmonary or suffocative type* the infection falls with especial stress upon the lungs. The temperature is high, the respirations rapid and hissing, and the condition suggestive of slow asphyxia. Consolidation of the lungs cannot be detected, but rhonchi are present everywhere, accompanied by fine crepitations. A stuporose condition may precede death or terminal convulsions may occur. The true *hæmorrhagic type* of measles is rare. In this the patient may bleed from the mucous membranes with hæmorrhages into the skin and subcutaneous tissues. Recovery takes place in some instances. Hæmorrhage into the rash, and confined to it, has not a very grave significance.

Complications—These are numerous, but those involving the respiratory tract, the middle ear and the bowel are the most important.

Laryngitis may accompany the onset, develop with the eruption or appear early in convalescence. Arising in the invasive stage it may simulate laryngeal diphtheria. Laryngitis is more common during the eruptive period, and may persist for some days—it may be complicated by laryngeal ulceration, sometimes by œdema of the

glottis; but necrosis of the laryngeal cartilages and abscess formation are rare. Severe laryngitis arising during convalescence should always arouse suspicion of diphtheria.

Bronchitis is often present during the eruptive stage, but bronchiolitis with spread ing broncho pneumonia is a much more serious complication, and is a common cause of death. Its incidence is favoured by adverse climatic conditions, overcrowding and contact with similar cases. It is generally attributed to secondary pneumococcal or streptococcal infection, but, especially when occurring early in the infection, may be due to *H influenzae*. This early broncho pneumonia is associated with a high temperature and considerable toxæmia. It is suffocative in type, and the lung signs are rather those of capillary bronchitis than of consolidation. During the eruptive stage, broncho pneumonia should be suspected if the temperature fails to fall or rises again with subsidence of the rash, and the pulse remains quick and respiration rapid. It may clear up in a week or 10 days, but often persists for weeks, or relapses. The temperature chart often shows remarkable daily remissions and exacerbations which may lead to suspicions of tuberculosis. The incidence of broncho pneumonia formerly about 13 per cent, has fallen with prophylactic chemotherapy to less than one quarter of this figure. Feeble infants succumb rapidly, and in those who recover convalescence is protracted.

True lobar pneumonia is uncommon. Massive collapse of the lower lobe of a lung has been described, its onset is sudden with intense dyspnoea, cyanosis and cardiac failure. It is distinguished from pneumonia by the feebleness of the breath sounds, upward displacement of the diaphragm and dislocation of the heart towards the affected side. Rarely mediastinal and subcutaneous emphysema have occurred. Effusions into the pleura have been noticed in some epidemics, and empyema may follow. Fibrosis of the lung and bronchiectasis often originate in the broncho pneumonia of measles.

Rheumatic arthritis with pericarditis, endocarditis and sometimes chorea has been known to supervene on measles.

Blepharitis and phlyctenular ulcers are common sequels. In cachectic children intense conjunctivitis may lead to ulceration and even perforation of the cornea.

The stomatitis of measles occasionally becomes ulcerative. Very rarely a gangrenous inflammation (noma) may attack the lips, cheeks, vulva or other parts. A discoloured patch appears on the mucous membrane and quickly ulcerates, extending both in area and in depth. A zone of inflammatory induration surrounds the lesion and a fetid odour is given off. Noma is terribly destructive both to soft parts and bone, and is very fatal. It occurs in debilitated children, and is attributed to secondary infection. Vincent's spirilla and fusiform bacilli are often present. It is said to be sometimes due to the Klebs Loeffler bacillus or to streptococci. Pronounced leucopenia may accompany it.

Otitis media was formerly a frequent and troublesome complication. Its incidence has been much reduced by prophylactic chemotherapy and is probably now not above 2.5 per cent. It may be catarrhal or suppurative, the suppurative form is more common in children, and is responsible for much chronic ear disease. Mastoid inflammation may occur, and deafness may result.

Cutaneous eruptions of eczematous, impetiginous or pustular type are common. Sometimes they are widespread, and very resistant to treatment.

Enlargement and suppuration of the cervical glands, enterocolitis and ascites are rarer complications.

Encephalo myelitis of a demyelinating type (see p. 1411) may occur towards the end of the first week with a course which is either rapidly fatal or tends to spontaneous recovery. Meningeal symptoms or convulsions may signalise its onset. Hemiplegia, aphasia, coma or mental defect may ensue but are rare. Myelitis, sometimes of the ascending form, has been known to occur in measles, also symptoms suggestive of disseminated sclerosis. Paralysis of extra-ocular muscles, papilledema and optic

atrophy have all been encountered. The mortality of encephalomyelitis is about 10 per cent.

Measles was formerly thought to favour the activation of tuberculous foci hitherto latent in the bronchial glands or elsewhere. It seems more likely that the coincidence of measles with the active stage of a primary tuberculous complex is the real danger, and caseous broncho-pneumonia, miliary tuberculosis of the lungs, or general tuberculosis with meningitis may follow immediately or occur after a quiescent period. Outbreaks of measles often occur in close association with whooping-cough, diphtheria and scarlet fever, which have a very similar seasonal incidence.

Relapse in measles is rare. Second attacks, although uncommon, undoubtedly occur, and some unfortunate individuals fail to acquire any lasting immunity. Fourth, and even seventh, attacks are known.

Diagnosis.—In the prodromal stage, measles may be mistaken for ordinary nasopharyngeal catarrh or even tonsillitis. If laryngitis is pronounced, and the child croupy, diphtheria may be simulated. Mastoid operations, excision of the tonsils and even of the appendix sometimes are performed precipitately before the true nature of the infection is recognised. Febrile symptoms and loss of weight during the incubation stage may be erroneously attributed to tuberculous infection. The prodromal scarlatiniform rash may lead to confusion with scarlet fever. These errors may be avoided by bearing in mind the possibility of measles, enquiring for exposure to infection, and particularly by a careful search for Koplik's spots and shottiness of the posterior cervical glands. The pre-eruptive fall of temperature and recession of the catarrhal symptoms before the appearance of the rash should be borne in mind, and not lead to premature relaxation of precautionary isolation.

In the eruptive stage, the fevers with which measles may be confused are rubella, small-pox and perhaps typhus.

Rubella is distinguished by the trivial nature and brevity of its prodromal symptoms; the slightness or absence of catarrh and cough; the insignificant fever; the absence of Koplik's spots and of stomatitis; and, especially, the presence of distinct and tender enlargement of the posterior cervical, mastoid and occipital glands. The rash of rubella is smaller, pinker and more discrete; but by fusion a scarlatiniform stage may supervene. The patient never feels or appears so ill as in ordinary measles. A previous attack of measles generally excludes that disease.

Small-pox may be heralded by a prodromal rash of morbilliform character, which may have a similar distribution to that of measles, save perhaps on the face. Catarrh, and true Koplik's spots, however, are absent, and the onset is more abrupt, and more likely to be signalled by such symptoms as backache, acute shivering, vomiting and severe prostration.

Measles may, on the other hand, be mistaken for the early eruptive stage of small-pox, for in both an illness for a few days may precede the appearance of a pronounced papular rash on the face and upper parts of the body. Catarrh, Koplik's spots and distribution of the rash about the ears, circumoral region and margins of the hairy scalp are in favour of measles. The temperature, too, continues to rise until the maximum efflorescence, whilst that of small-pox is unique in that it begins to fall on the third day with the outbreak of the rash. As the rash develops, the shottiness of the small-pox papules and the peculiarities of their distribution and evolution become apparent.

Typhus fever may be simulated by measles when the rash of the latter is receding and dusky, and lung complications are present; but the rash of typhus rarely invades the face, which is always affected in measles. The Weil-Felix reaction is a valuable indication of typhus.

Septic rashes in scarlet fever are often morbilliform; but their distribution does not conform to that of the measles rash. *Serum rashes*, *food rashes* and *drug eruptions* may assume a measly character; but these rashes often prove to be polymorphic

when the whole body is examined, as it should be, and, besides, other signs of measles are wanting.

The *macular syphilide* is distinguished by the absence of respiratory catarrh and of Koplik's spots. History of exposure to venereal infection, a chancre and the accompanying throat symptoms afford a clue. The Wassermann test is positive.

Prognosis.—In different epidemics the death-rate varies greatly. Measles is most fatal to infants and young children, 70 per cent. of the mortality occurring in children under 3 years of age. After the fourth year the death-rate is low. In the London Fever Hospitals the mortality rate was 5.6 per cent. for 1931-1932; in 1942 it had fallen to 0.38 per cent. and has since remained at this level. Rickets, tuberculosis, congenital syphilis, malnutrition and chronic bowel complaints are unfavourable factors, and the disease is more fatal among the poor. In the cold season of the year the tendency to respiratory complications is more marked and the fatality rate is nearly double that in the summer months, when enterocolitis is more common. When the infection occurs in conjunction with whooping-cough or chronic lung disease the mortality is high. Diphtheria is apt to assume the laryngeal form, and is an especially fatal complication. Considerable toxæmia with high fever, cyanosis, muscular tremor and diarrhoea point to a severe attack. Laryngitis, capillary bronchitis and broncho-pneumonia are serious. Cerebral symptoms, such as prolonged stupor or convulsions, are of bad augury. Remarkable recovery has been noticed in some cases of ascending myelitis.

Treatment.—**PROPHYLACTIC.**—Measles is chiefly disseminated by schools. The difficulty in controlling outbreaks of measles arises from the fact that it is extremely infectious, and the infectivity is present in virulent form for 4 or 5 days before the rash appears. Notification and school closure have been tried with poor results. The best method is to make provision for the early recognition of suspicious symptoms in contacts for a period covering the ninth to the sixteenth day after the occurrence of the first case. Exclusion of contacts from school has proved ineffective and quarantine is usually limited to children under the age of 6 years who have not had measles.

In ward outbreaks children who have not had measles should be passively immunised and, if possible, isolated, or, at all events, segregated in small groups.

Serum prophylaxis.—Intramuscular injection of the blood serum of healthy convalescents from measles into susceptible contacts produces a *passive* immunity, which lasts about a month. Injection during the first 5 or 6 days of the incubation period prevents measles if the dose is adequate. Injection after the sixth and before the ninth day will modify the severity of attack, and allow the development of an *active* immunity which is lasting. Dried convalescent serum is also effective.

The dose is 2 ml. for each year of a child's age to a maximum of 10 ml.; more is needed for adults or if the serum is injected late. In children under 3 years of age it is better to prevent the attack altogether. The most potent serum is obtained from the sixth to the ninth day after desquescence. The donor must be free from syphilis, malaria and tuberculosis, and must not be incubating any other infectious disease.

The serum of adults, presumed to have had measles at some previous time, but not recently, is of some value, but the dose should be doubled. If citrated whole blood is substituted there may be danger of Rh sensitisation. A placental globulin extract has been prepared for use in the same way but reactions are severe.

If measles follows the subcutaneous injection of immune serum the rash fails to erupt at the site of injection; this is the *Debré phenomenon*. Immune serum does not blanch the developed rash. A disquieting feature is the occasional occurrence of infective hepatitis (*homologous serum jaundice*) after the administration of convalescent measles serum, sometimes after so long an interval as 3 months. If obtainable, the use of pooled gamma globulin which represents a 25-fold concentration of the serum and can be safely heated to 57° C. for 4 hours should prevent this. The dose is 0.1

ml per pound of body-weight This pooled globulin has proved quite as effective as convalescent serum

Systematic taking of temperatures and examination for Koplik's spots and catarrh facilitate early detection of the disease The wilful exposure of children to measles is unjustifiable, as the nature of the resulting attack can never be predicted.

Sixteen days' quarantine from the date of last exposure to infection is usually deemed sufficient, but, owing to the trivial nature of the prodromal symptoms, it is better, in the case of schools, if quarantine is imposed at all, to allow a period of 3 weeks to elapse, especially if serum prophylaxis has been attempted Convalescent patients in the absence of complications are quite free from infectivity at the end of a fortnight and possibly even a week from the appearance of the rash

CURATIVE—The patient must be confined to bed during the febrile, and also during the prodromal stage, if this is recognised in time The sick-room should be kept at a temperature of 60° to 65° F, and ventilation effected by means of open windows, an open fire is also an advantage The photophobia calls for screening from direct light Clothing should be light and consist of a flannel or woollen night-dress; this is sufficient to prevent chill, allows the respiratory muscles full play and encourages the evaporation of perspiration Strict attention should be paid to cleansing the mouth and teeth, and the regulation of the bowels During the febrile stage the diet should be restricted to milk, diluted if necessary with barley water Tea may be allowed, and fruit juices or barley water given to assuage the thirst

Twice a day during the febrile period the patient should be washed with tepid water, but should the attack assume a toxic form, accompanied by high fever and delirium, cold sponging or the use of the cold pack is advisable

Laryngitis in the early stage is relieved by steam and the use of a simple expectorant mixture, to which a sedative may be added The croupy symptoms usually subside without necessitating tracheotomy or intubation The possibility of the presence of diphtheria renders a bacteriological examination essential

Laryngitis which persists after the eruption may be alleviated by the inhalation of compound tincture of benzoin or lysol in the strength of 60 minims to the pint of boiling water The cough is relieved by a simple linctus, or one containing codeine or other sedative Late laryngitis if diphtheritic needs antitoxin Bronchitis and broncho-pneumonia call for prompt treatment Antibiotics, either penicillin or aureomycin, should be prescribed immediately If the cough is dry and irritating, steam often relieves An expectorant mixture containing ipecacuanha and a small quantity of potassium iodide is useful Sometimes a single mustard and linseed poultice gives great relief As the cough becomes looser, steam should be discarded and free ventilation arranged It is well to separate cases with broncho-pneumonia from others, as the condition is believed to be infectious Treatment of the broncho-pneumonia of measles in the open air, where circumstances and weather permit, gives excellent results Oxygen is valuable where there is much respiratory distress and cyanosis

Sulphadimidine given for 6 days from the appearance of the rash reduces the incidence of broncho-pneumonia and otitis media to a trivial figure

Conjunctivitis should be treated by bathing the eyes with boric lotion and the application of boric ointment to the lids In severe cases, penicillin or drops of silver nitrate solution, gr 2 to the oz, should be instilled night and morning, or 2 to 10 per cent solutions of silver protein used Should the cornea ulcerate, atropine drops should be employed and oculent hydrarg oxid applied Eye bandages are undesirable

Stomatitis usually subsides quickly, the mouth should be cleansed with a lotion containing chlorate of potash (gr 10 to 1 fl oz) Ulceration due to Vincent's organisms should be treated with intramuscular penicillin The supervision of noma necessitates bacteriological examination, the use of penicillin, neocarsphenamine or

when the whole body is examined, as it should be, and, besides, other signs of measles are wanting.

The *macular syphilide* is distinguished by the absence of respiratory catarrh and of Koplik's spots. History of exposure to venereal infection, a chancre and the accompanying throat symptoms afford a clue. The Wassermann test is positive.

Prognosis.—In different epidemics the death-rate varies greatly. Measles is most fatal to infants and young children, 70 per cent. of the mortality occurring in children under 3 years of age. After the fourth year the death-rate is low. In the London Fever Hospitals the mortality rate was 5.6 per cent. for 1931-1932; in 1942 it had fallen to 0.38 per cent. and has since remained at this level. Rickets, tuberculosis, congenital syphilis, malnutrition and chronic bowel complaints are unfavourable factors, and the disease is more fatal among the poor. In the cold season of the year the tendency to respiratory complications is more marked and the fatality rate is nearly double that in the summer months, when enterocolitis is more common. When the infection occurs in conjunction with whooping-cough or chronic lung disease the mortality is high. Diphtheria is apt to assume the laryngeal form, and is an especially fatal complication. Considerable toxæmia with high fever, cyanosis, muscular tremor and diarrhoea point to a severe attack. Laryngitis, capillary bronchitis and broncho-pneumonia are serious. Cerebral symptoms, such as prolonged stupor or convulsions, are of bad augury. Remarkable recovery has been noticed in some cases of ascending myelitis.

Treatment.—**PROPHYLACTIC.**—Measles is chiefly disseminated by schools. The difficulty in controlling outbreaks of measles arises from the fact that it is extremely infectious, and the infectivity is present in virulent form for 4 or 5 days before the rash appears. Notification and school closure have been tried with poor results. The best method is to make provision for the early recognition of suspicious symptoms in contacts for a period covering the ninth to the sixteenth day after the occurrence of the first case. Exclusion of contacts from school has proved ineffective and quarantine is usually limited to children under the age of 6 years who have not had measles.

In ward outbreaks children who have not had measles should be passively immunised and, if possible, isolated, or, at all events, segregated in small groups.

Serum prophylaxis.—Intramuscular injection of the blood serum of healthy convalescents from measles into susceptible contacts produces a *passive* immunity, which lasts about a month. Injection during the first 5 or 6 days of the incubation period prevents measles if the dose is adequate. Injection after the sixth and before the ninth day will modify the severity of attack, and allow the development of an *active* immunity which is lasting. Dried convalescent serum is also effective.

The dose is 2 ml. for each year of a child's age to a maximum of 10 ml.; more is needed for adults or if the serum is injected late. In children under 3 years of age it is better to prevent the attack altogether. The most potent serum is obtained from the sixth to the ninth day after defervescence. The donor must be free from syphilis, malaria and tuberculosis, and must not be incubating any other infectious disease.

The serum of adults, presumed to have had measles at some previous time, but not recently, is of some value, but the dose should be doubled. If citrated whole blood is substituted there may be danger of Rh sensitisation. A placental globulin extract has been prepared for use in the same way but reactions are severe.

If measles follows the subcutaneous injection of immune serum the rash fails to erupt at the site of injection; this is the *Debré phenomenon*. Immune serum does not blanch the developed rash. A disquieting feature is the occasional occurrence of infective hepatitis (*homologous serum jaundice*) after the administration of convalescent measles serum, sometimes after so long an interval as 3 months. If obtainable, the use of pooled gamma globulin which represents a 25-fold concentration of the serum and can be safely heated to 57° C. for 4 hours should prevent this. The dose is 0.1

ml. per pound of body-weight. This pooled globulin has proved quite as effective as convalescent serum.

Systematic taking of temperatures and examination for Koplik's spots and catarrh facilitate early detection of the disease. The wilful exposure of children to measles is unjustifiable, as the nature of the resulting attack can never be predicted.

Sixteen days' quarantine from the date of last exposure to infection is usually deemed sufficient, but, owing to the trivial nature of the prodromal symptoms, it is better, in the case of schools, if quarantine is imposed at all, to allow a period of 3 weeks to elapse, especially if serum prophylaxis has been attempted. Convalescent patients in the absence of complications are quite free from infectivity at the end of a fortnight and possibly even a week from the appearance of the rash.

CURATIVE.—The patient must be confined to bed during the febrile, and also during the prodromal stage, if this is recognised in time. The sick-room should be kept at a temperature of 60° to 65° F., and ventilation effected by means of open windows; an open fire is also an advantage. The photophobia calls for screening from direct light. Clothing should be light and consist of a flannel or woollen night-dress; this is sufficient to prevent chill, allows the respiratory muscles full play and encourages the evaporation of perspiration. Strict attention should be paid to cleansing the mouth and teeth, and the regulation of the bowels. During the febrile stage the diet should be restricted to milk, diluted if necessary with barley water. Tea may be allowed, and fruit juices or barley water given to assuage the thirst.

Twice a day during the febrile period the patient should be washed with tepid water; but should the attack assume a toxæmic form, accompanied by high fever and delirium, cold sponging or the use of the cold pack is advisable.

Laryngitis in the early stage is relieved by steam and the use of a simple expectorant mixture, to which a sedative may be added. The croupy symptoms usually subside without necessitating tracheotomy or intubation. The possibility of the presence of diphtheria renders a bacteriological examination essential.

Laryngitis which persists after the eruption may be alleviated by the inhalation of compound tincture of benzoin or lysol in the strength of 60 minims to the pint of boiling water. The cough is relieved by a simple linctus, or one containing codeine or other sedative. Late laryngitis if diphtheritic needs antitoxin. Bronchitis and broncho-pneumonia call for prompt treatment. Antibiotics, either penicillin or aureomycin, should be prescribed immediately. If the cough is dry and irritating, steam often relieves. An expectorant mixture containing ipecacuanha and a small quantity of potassium iodide is useful. Sometimes a single mustard and linseed poultice gives great relief. As the cough becomes looser, steam should be discarded and free ventilation arranged. It is well to separate cases with broncho-pneumonia from others, as the condition is believed to be infectious. Treatment of the broncho-pneumonia of measles in the open air, where circumstances and weather permit, gives excellent results. Oxygen is valuable where there is much respiratory distress and cyanosis.

Sulphadimidine given for 6 days from the appearance of the rash reduces the incidence of broncho-pneumonia and otitis media to a trivial figure.

Conjunctivitis should be treated by bathing the eyes with boric lotion and the application of boric ointment to the lids. In severe cases, penicillin or drops of silver nitrate solution, gr. 2 to the oz., should be instilled night and morning, or 2 to 10 per cent. solutions of silver protein used. Should the cornea ulcerate, atropine drops should be employed and oculent hydrarg. oxid. applied. Eye bandages are undesirable.

Stomatitis usually subsides quickly; the mouth should be cleansed with a lotion containing chlorate of potash (gr. 10 to 1 fl. oz.). Ulceration due to Vincent's organisms should be treated with intramuscular penicillin. The supervention of noma necessitates bacteriological examination, the use of penicillin, neosarsphenamine or

the appropriate antitoxin and surgical interference in the way of cauterisation or free excision and local application of zinc peroxide paste or permanganate crystals. Enterocolitis is managed on the same lines as infantile epidemic diarrhoea.

Convulsions and encephalomyelitis are treated by sedatives and lumbar puncture, repeated if the cerebrospinal fluid is under increased pressure. Intramuscular or intravenous injection of 10 ml. of blood serum from a recently recovered case with this complication, if obtainable, seems worthy of a trial.

In an uncomplicated case of measles the patient may be allowed up 2 or 3 days after the temperature subsides. Supervision should be exercised during the convalescence of severe cases, and the possibility of later tuberculosis borne in mind. Ear discharges call for skilled treatment, as they may become chronic (see also directions on p. 47).

RUBELLA

Synonyms.—German Measles, Rotheln.

Rubella is quite distinct from ordinary measles and from scarlet fever. It protects only against itself. Amongst the exanthemata it is distinguished by its long incubation period, its short invasive stage, its characteristic rash and adenitis, its benign course and the time of its seasonal prevalence.

Ætiology.—The infectivity is less than that of measles and of short duration. Like measles it is infectious for a day or two before the eruption appears. Infection is by droplet spray and is facilitated by close contact. There is no evidence that the disease is spread by fomites. Transmission through an intermediary cannot be considered proved. The infective agent is presumed to be a filtrable virus.

Rubella is prevalent in the first half of the year. Cases increase from January to a maximum in May and June or sometimes in August or September. A series of local outbreaks usually occurs, determined by the aggregation of a number of unprotected young adults. A more or less pronounced epidemic wave occurs every third or fourth year. The maximum incidence is at a later age period than that of measles, but even the youngest infants have been known to take the disease. Its frequency much diminishes after the age of 30. Sex is without influence.

The occurrence of rubella in the first 2 or 3 months of pregnancy is known to favour the incidence of cataract, heart malformation, deaf-mutism and other congenital defects in the child. These may be multiple. The risk of a live child with congenital defects is about 25 per cent. and the frequency of stillbirth about the same when the mother contracts rubella within the first 3 months of pregnancy. Abortion, frequent in measles, is rare in rubella.

Symptoms.—The incubation period, although variously stated to be from 7 to 22 days, is usually 17 or 18 days.

Premonitory symptoms are mild or altogether absent, but a short catarrhal stage usually occurs, the rash making its appearance within 24 hours. Rarely a longer prodromal period of ill-defined febrile illness occurs before the eruption. The characteristic tender adenitis of the mastoid, occipital, cervical or other lymph glands can, more often than not, be detected for a day or two, exceptionally even a week or longer, before the appearance of the rash.

The rash has two stages. Macular, slightly papular and morbilliform in its progress, it frequently fuses and becomes scarlatiniform in its final stage. Discrete spots first appear on the face or neck; they invade the circumoral region and may be found behind the ears and on the scalp. Sometimes they are first found on the wrists, chest, shoulders or even on the legs. They are smaller than the papules of measles, pale pink in colour and tend to cluster in smaller groups. The rash quickly extends to the trunk and limbs and in most cases as quickly fades. On the second

day the face is no longer spotty but appears diffusely erythematous ("sunburnt"). Sometimes the outbreak of the eruption is halting in its progress. The scarlatiniform stage is not developed in all attacks, it is due to the fusion of the discrete elements, and is generally best marked on the trunk, especially so on the back. It becomes most apparent on the second day of the eruption. The rash of rubella rarely lasts more than 72 hours and hardly stains the skin, thus contrasting with measles.

Stomatitis is insignificant, and Koplik's spots never occur. The tonsils may be slightly swollen and reddened, sometimes a follicular exudate is present. Some degree of pharyngeal catarrh is evident, and the tongue may be lightly coated. A fine vesiculation and congestion of the soft palate are often seen, and the orifices of Stenson's ducts may be vividly injected. Sometimes the gums are injected and tender. The conjunctivæ are pink and the eyes slightly suffused. Photophobia is rare.

Fever is slight, even when the rash is intense. Often there is no fever at all. The pulse and respiration rates are only increased in proportion to the febrile disturbance.

A tender adenitis is very distinctive. The mastoid and occipital glands may rapidly attain the size of peas, the posterior cervical glands are also enlarged, frequently too those in the axillæ and groins. The enlarged glands are firm, tender and discrete, they never suppurate. As a rule resolution takes place rapidly when the rash subsides. Particularly in children, the spleen may become palpably enlarged. The urine presents no special characteristics.

As in the case of morbilli, a transient polymorphonuclear leucocytosis occurs during the incubation period, but a leucopenia with a relative increase of lymphocytes is found in the eruptive stage. Very distinctive is a high percentage of plasma cells, 15 to 20 per cent, on the fourth and fifth days of the attack, when the neutrophils are at their lowest.

Convalescence is remarkably speedy. Slight furfuraceous desquamation may occur.

Complications—Complications and sequelæ are, as a rule, absent. When they do occur they are trivial and take the form of mild recurrent sore throat, rheumatism, slight laryngitis, bronchial catarrh or transient albuminuria. In some outbreaks benign polyarthritis has been a feature. Otitis is very rare, and meningeal symptoms, encephalomyelitis, or polyneuritis, rarer still.

On occasions, epidemics of rubella of more severe type, approximating in symptoms and sequelæ much more closely to measles, have been described.

Diagnosis—The disease has a similarity to both measles and scarlet fever especially when the latter occurs in a mild form. In addition, the rash of rubella must be distinguished from toxic and drug rashes, from the eruption of secondary syphilis, from glandular fever and from certain skin diseases.

Measles is differentiated by the following points. Its incubation period is shorter, being 14 days from exposure to the appearance of the rash, cough and catarrhal symptoms are marked, the mucous membrane of the mouth is inflamed and Koplik's spots are present. The rash appears later, is darker, more persistent and stains. There is no late scarlatiniform stage. Fever is more pronounced, prostration more evident and the mastoid and occipital glands are not especially enlarged. Pulmonary complications are much more likely to occur.

Rubella is often mistaken for scarlet fever. Distinctive points in favour of the latter are the short incubation period, the occurrence of such initial symptoms as vomiting, marked faucial inflammation, shivering or severe headache. The fever is high at onset and the pulse disproportionately rapid. The circumoral region is free from rash, and by the fourth day the tongue has peeled. The occurrence of such sequelæ as cervical adenitis and nephritis, also typical pinhole or lamellar desquamation, will clinch the diagnosis. Even in the scarlatiniform stage of rubella, discrete mealy elements may generally be detected about the advancing edges of the rash.

on the forearms, wrists, legs and ankles. An eruptive fever which simulates measles at its onset and scarlet fever later, is generally rubella. Occasionally glandular fever (*qv*) resembles rubella.

Toxic, enema and drug rashes may bear a resemblance to the rash of rubella, but, as a rule, these rashes are very irregular in their distribution and polymorphic in character. The characteristic tender occipital and mastoid glandular enlargement and slight catarrh of rubella are absent.

Of skin diseases, erythema scarlatiniforme and pityriasis rosea are sometimes mistaken for rubella. The first named bears a greater resemblance to scarlet fever, unlike rubella it avoids the face, does not give rise to swelling of the mastoid and occipital glands, and shows a great tendency to recur.

Pityriasis rosea, itself possibly an infective fever, is distinguished by a herald patch which precedes the general eruption, and the fact that the latter usually appears first on the upper part of the trunk. The rash often shows commingled macular and ringed lesions. The patches are slightly scaly and are decidedly larger and more persistent than the papules of rubella. They desquamate in a characteristic manner from their centres, which are fawn coloured, towards the margins, which are slightly elevated, darker and ringed by a collarette of scales. There is no catarrh and no conspicuous glandular enlargement about the head.

Secondary syphilides bear a superficial resemblance to the rash of rubella, but are distinguished by the presence of a primary sore, the characteristic throat and the conspicuous increase in size, and shottiness of the glands in the vicinity of the chancre. The Wassermann reaction is positive.

The Paul Bunnell reaction will distinguish glandular fever.

Prognosis—Recovery is the rule, second attacks are known, but not common, and relapse is very rare.

Treatment—**PROPHYLACTIC**—As the incubation period is long a quarantine of 3 weeks is theoretically necessary for contacts, but is rarely imposed. They should be supervised from the tenth to the twenty first day from exposure to infection. Early warning of the imminence of attack may be given by slight enlargement and tenderness of the mastoid and occipital glands.

Special precautions against infection should be adopted in early pregnancy. If convalescent serum or gamma globulin can be obtained serum prophylaxis should be attempted. This protection lasts but a few weeks, so repetition is necessary in those still exposed to infection.

CURATIVE—The patient should be isolated and preferably kept in bed until all symptoms have subsided. In 7 days, possibly sooner, infectivity has ceased, provided there is no persistence of faucial, nasal, respiratory or other symptoms.

SMALL-POX

Synonym—Variola

Definition—An acute, highly infectious specific fever, characterised by a definite incubation period and a peripherally distributed, deep seated, disfiguring eruption which passes through the stages of papule, vesicle, pustule and crust. A pre eruptive, toxic or septicæmic, and an eruptive, or focal, phase are recognised.

Ætiology—All races, both sexes and persons of every age are susceptible if unprotected by a previous attack, or by efficient vaccination. This universal liability is most evident when the disease is introduced for the first time into a new community, under such conditions it may decimate the population. The present day incidence in adults is accounted for by vaccination in infancy, in endemic centres it was, prior to the introduction of vaccination, a disease of early childhood.

For centuries endemic in Asia, small pox has at times been epidemic in every

civilised country, following trade routes and the channels of communication. It is more severe in hot climates, but its virulence has always varied greatly in different localities and different outbreaks. Coloured races take it badly. Unlike scarlet fever and measles, it frequently attacks infants at the breast.

When small-pox occurs during pregnancy, the disease in the mother tends to assume a confluent or hæmorrhagic type and infection of the fœtus is common but not inevitable. Abortion or premature delivery is to be expected in all severe attacks. The fœtus contracts the disease *in utero*, usually during the pre-eruptive (septicæmic) stage in the mother, the incubation period being shortened. Sometimes fœtal infection is delayed and may even occur at the time of separation of the placenta. Few of the children survive, sometimes they show the rash or its scars at birth.

In temperate climes most outbreaks of small pox occur during the winter and spring, and die out with the commencement of summer. In the tropics periods of drought predispose to epidemics. Second attacks are rare. Vaccination gives complete immunity for some years and partial immunity usually persists afterwards. Complete natural immunity is very rare, as also is a persistent susceptibility in which vaccination or a previous attack fails to protect.

Infection with small pox is, almost certainly, through the respiratory tract, and may be direct or indirect, *i.e.* by contact, which need not be very close, with a patient suffering from the disease or through the medium of objects infected by the sick person. Intermediaries may carry the contagium in their clothing or in their hair. The greater incidence in the neighbourhood of small pox hospitals suggests the possibility of aerial convection of the virus for considerable distances, perhaps exceeding a mile, but the influence of human carriers in these cases is hard to eliminate. Bedding, clothing, rags and articles of merchandise, such as cotton, may retain their infectivity for considerable periods of time, especially when stored. Transmission by flies and domestic animals is regarded as a possibility.

With the exception of the pre-eruptive stage of hæmorrhagic small pox, the infectivity is slight at the time of the symptoms of onset, and is much greater when the eruption appears. Infectivity in the early stages is, by some attributed to primary and unrecognised lesions in the respiratory tract. It continues until all the scabs have separated. The virus is very resistant to desiccation and long persists in the dry crusts and seeds. Crusts dried *in vacuo* have been found infective after more than 2 years. Corpses of those recently dead from small pox can transmit the disease. Tramps are often responsible for the conveyance of infection from one locality to another.

There is no doubt that small pox is due to a filtrable virus. Minute but characteristic, intracellular bodies are found in the epithelial cells of the pocks of small pox and vaccinia, and also in the cornea of the rabbit, after scarification with the virus of these diseases. They are known as *Guarnieri bodies* and are aggregations of the 'elementary bodies' of Paschen. The elementary bodies of small pox and of its variant *variola minor*, are agglutinated by the sera of patients convalescent from either form of the disease.

Pathology—The cutaneous lesion of small pox lies in the deeper layers of the epidermis. Vesiculation is due to serous exudation between and into the cells. Loculation is caused by vertical strands of the ruptured epithelial cells which radiate from the base of the pock. The tenseness of the vesicle and tethering of the covering by this reticulum cause the pock to be umbilicated. In malignant attacks, where the pocks are flaccid, and in the old and debilitated, umbilication is often absent. With pustulation the fibres of the reticulum are destroyed and the pock becomes dome-shaped. Multinucleated giant cells are formed in the prickle cell layer. The suppuration is attributed to secondary infection with hæmolytic streptococci or with staphylococci. On mucous membranes the vesicles rupture almost as soon as formed and are rapidly converted into shallow erosions.

The chief blood change is an initial leucopenia, followed after the first week by a leucocytosis in which mononuclear cells preponderate. Secondary anæmia may be pronounced. In malignant small-pox the presence of myelocytes and normoblasts with a thrombocytopenia has led to an incorrect diagnosis of acute leukaemia.

The post-mortem appearances are those usually found in acute infective processes. The rash persists, the liver is often much enlarged, the spleen swollen, and the lungs broncho-pneumonic. Particular attention has been drawn to the presence of local necroses in the liver, testicles and bone marrow. These are often infiltrated with mononuclear basophil cells. Interstitial infiltrations of the kidneys also occur.

In hæmorrhagic small-pox, petechial and purpuric hæmorrhages are found in the skin, mucous membranes, lungs and other viscera, sometimes also in the retro-peritoneal tissues and the roots of the mesenteries.

Symptoms—*Unmodified or natural small-pox, Variola major.*

Period of incubation—Taking the first symptoms of invasion, this is from 10 to 14 days. The average period is 12, or counting to the appearance of the rash, 14 days. Extremes of 5 to 23 days are mentioned but are rare. With increasing virulence the incubation period tends to shorten. In inoculated small-pox the generalised eruption appears on the eighth to the eleventh day.

Period of invasion—toxic or septicæmic stage—In a typical unmodified attack the invasive symptoms are sudden and of great intensity. The most prominent are severe chills or rigors, marked pyrexia, severe frontal headache and intense pain across the loins. The temperature quickly reaches a maximum of 103° to 104° F and there is severe prostration. Retching and vomiting may occur, particularly in children. Delirium, mental symptoms and even suicidal tendencies occasionally accompany this stage. With these severe symptoms are coupled more ordinary febrile manifestations, such as anorexia, thirst, coated tongue and disturbed sleep. The breath is offensive, the skin usually hot and dry but sometimes perspiring, and the bowels constipated.

There are, however, mild attacks in which the symptoms of invasion are much less severe, and even in more severe attacks pain across the loins is by no means constant. Mild invasive symptoms usually presage a mild course, with a severe invasion the attack is generally, although not invariably, grave.

Prodromal rashes belong to the toxic or septicæmic stage, and may precede the proper eruption for 1 or 2 days, but they are not always present. There are two types, one purely erythematous, the other petechial or hæmorrhagic with or without accompanying erythema. The pure erythemas are of a bright red or dusky-purplish colour and may appear in the femoral triangles, the axillæ or on the trunk, where they are often patchy and evanescent, or be limited to the bony prominences and extensor surfaces of the limbs. They may suggest the rash of scarlet fever, or, less frequently, bear a superficial resemblance to that of measles. The hæmorrhagic or petechial rash, which often has at first a dusky erythematous background, is more characteristic. It appears in the groins, which are stippled with small petechiæ, invades the thighs for an inch or two and extends in an ill-defined manner on to the abdomen (*bathing drawers rash*). Sometimes it extends towards the axillæ and may be found on the back of the neck and flexures of the knees. The petechial rashes are persistent and indicate a severe attack. The erythemas are fugitive and of good prognostic import, the only exception is a very brilliant universal oedematous erythema of face, trunk and limbs known as the *astacoid*, or *lobster*, rash which sometimes ushers in hæmorrhagic small pox. Later this may be replaced by livid sheets of deep subcutaneous hæmorrhage.

Eruption or focal stage—Distribution—On the third day the invasion is at its height and the focal eruption should appear. In malignant attacks it may erupt earlier. It is not necessarily profuse, indeed, in mild and modified attacks it may be limited to a few lesions on the distal parts of the limbs and on the face. Whether scanty or

profuse, the rash is centrifugal in distribution, appearing first on the forehead near the scalp, and on the temples, then on the backs of the wrists and hands, and a day later about the ankles and feet. Its extension is rapid and symmetrical and its elements deeply seated in the skin, uniform in size and more or less circular. In marked contrast to the prodromal petechial rash the full efflorescence is least profuse on the abdomen and groins, scanty on the chest, more evident on the back, especially across the shoulders, increasing as it descends the arms to thicken on the extensor aspects of the wrists and hands. Most profuse of all is the outbreak on the supraorbital, malar and nasal prominences of the face. The rash reaches the lower extremities within 24 hours and here is most evident about the ankles and feet, where it may still be in the papular stage whilst that on the face has become vesicular. Meantime the lesions multiply on the parts already affected, the eruption becoming thick on the face and perhaps on the scalp whilst still scanty on the parts involved later. In 3 days it will have attained its full density and typical distribution, but the earliest lesions will be in a more advanced stage of development. It is highly characteristic of the focal eruption of small pox to avoid depressions, flexures and protected flexor surfaces such as the armpits, groins, flanks, orbital hollows, supraclavicular fossæ and flexor aspects of the toes. Abnormal irritation by bands of clothing, irritants, scratching, vaccination or exposure to sun and weather may determine a profuse eruption on areas where, ordinarily, poeks are scanty. The poeks, too, tend to aggregate along prominent bones and tendons but may strangely avoid the prominences formed by the clavicles and the malleoli.

Evolution and maturation—On its *first* day the rash consists of small dull-red macules. Within 24 hours these become papules which feel shotty when pinched up between the finger and thumb, on the face, hands or forearms. On the *third* day many papules have become vesicles, but vesiculation may be recognised on the summits of the papules at an even earlier stage. By the *fourth* or *fifth* day the eruption is completely vesicular and the toxæmic symptoms and fever of onset may have subsided. The vesicles, circular in outline, slowly increase in size and become surrounded by red areolæ. They are now the size of split peas, greyish, and set in rather than on the skin. Umbilication is evident and loculation is proved by failure to collapse when transfixed by a sterile needle. The contents of the vesicles remain clear for 24 hours only, they then become purulent, so that by the *fifth* day pustules are evident on the face and by the *eighth* day are universal. With pustulation, the poeks soften, become flat-topped and lose their areolæ.

Recession of fever with constitutional symptoms and often delirium, the *second* *ary suppurative fever*, accompanies the process of suppuration or maturation. A marked inflammatory œdema of the skin may now appear, causing the features to become swollen and expressionless and impeding the movements of the hands and fingers. Much tenderness and itching may accompany this œdema. Suppuration destroys the loculation of the vesicles and also obliterates umbilication. Adjacent lesions, particularly on the face and hands, may run together in the vesicular and pustular or even the papular stage—a process which produces the confluent rash, a sign of severe infection.

On the *ninth* and *tenth* day the pustules begin to desiccate, some first rupture or are torn by scratching, and collapse. Brown or black crusts result which separate by the end of the thirteenth or fourteenth day, but where the skin is very thick, as on the palms and soles, the dried up unruptured pustules may form deep seated "seeds," which may take weeks to work their way to the surface and remain infectious for months.

To summarise the rash is papular on its first and second days, vesicular on the third and fourth, pustular on the fifth and sixth and thereafter desiccating. A rash which remains papular after the third day or is fully vesicular by the second day is unlikely to prove to be due to small-pox.

The cutaneous eruption is accompanied by an outcrop of greyish infiltrations on the conjunctivæ and mucous membranes of the mouth, tongue, nose and pharynx. In severe cases the larynx, bronchi, gullet and even the stomach and small intestine may also be affected. On the mucous membranes infiltrations and vesicles are soon transformed into shallow ulcers. Vesiculation may be observed on the palate, whilst the lesions are still indeterminate on the skin. In consequence of the eruption the eyelids, fauces and tongue become sore, the nose is obstructed and deglutition is painful. Implication of the larynx will cause hoarseness or aphonia and even dangerous œdema. The mucous membranes of the vulva, vagina, prepuce and rectum do not escape.

A mild generalised superficial adenitis is common and the spleen may be palpable. The fever of invasion reaches its acme with the appearance of the rash, then it falls, but not immediately. It is generally normal by the fifth day of the attack, often before this. Small-pox thus differs from other eruptive fevers in that the temperature falls during the appearance of the focal eruption. At this stage, in the milder attacks with scanty rash, the patient may attempt to resume his ordinary occupation, and, in modified cases, very little further febrile disturbance may ensue. Ordinarily, however, the secondary suppurative fever now sets in and reaches its acme about the ninth or tenth day of the disease. Its duration in the more severe cases is from 10 days to a fortnight. In severe and confluent small-pox the remission of temperature in the vesicular stage may be absent.

The pulse and respirations are quickened proportionately to the degree of fever present, but in grave attacks the respirations become more rapid, shallow and irregular, and the pulse accelerated and feeble. In malignant and hæmorrhagic infections death may occur from toxæmia within the first week. In the gravest cases a subnormal temperature accompanies the toxic stage and death may result from circulatory failure, even within the first 24 hours, the mind remaining clear.

The urine is febrile in character. Some albumin may be present, and a diazo-reaction may be obtained.

Owing to the depth of the lesions in the skin, depressed scars are left, the amount of pitting depending on the degree of destruction of the true skin. The pits show a reddish staining which may persist for months. Some desquamation may accompany the separation of the crusts, particularly on the feet and hands. The hair often falls out freely. The nails may be shed. Convalescence is, in favourable cases, rapid and complete, but may be much delayed when sepsis has supervened.

VARIETIES.—Small-pox may be severe, modified or naturally benign.

Severe types of small-pox.—In addition to malignant or severely toxic attacks these include the confluent and the hæmorrhagic varieties. *Confluent small-pox* is distinguished from *discrete small-pox* by fusion of the lesions, particularly on the face and hands. The rash may fuse while still papular, but more commonly does so in the vesicular and pustular stages. In such cases the toxæmia is severe and the remission of symptoms before the stage of pustulation may be absent or ill-marked. Delirium is common, and the secondary fever high. *Inflammatory œdema* is very marked, the features may become quite unrecognisable and the confluent pocks may form a continuous sheet of pus. Severe conjunctivitis, nasal obstruction, salivation, cough, aphonia and diarrhœa are common. Some patients pass into a typhoid condition. An offensive odour emanates from the body, circulatory failure is progressive and death may occur towards the end of the second week.

Hæmorrhagic small-pox.—In the earliest and most malignant variety (*Purpura variolosa*), the incubation period may not exceed 7 or 8 days. Purpuric flecks and patches often appear in the skin before the development of the eruption, but spots of greyish infiltration may already be appearing in the buccal and palatine mucosa and rapidly become pseudo-membranous and confluent. The cutaneous hæmorrhages are accompanied by subconjunctival hæmorrhages, hæmaturia and bleeding from the

mucous membranes. Initial symptoms, in particular backache and prostration, are severe, and prodromal rashes common. The respiration is hurried and the breath sickeningly fetid, but the temperature not necessarily very high. Death may occur before the outbreak of the proper eruption gives a clue to the nature of the infection, but often towards the end careful inspection may detect a few papular elements of the focal rash, possibly lying in a prodromal erythema.

In other cases the bleeding manifests itself later, and accompanies the focal eruption, in the form of petechiæ or of circular spots between the lesions and infiltrations of their bases staining their contents (*Variola hæmorrhagica pustulosa*). The pocks are often badly developed, confluent and of a violaceous hue. Bruises form easily in the skin, and hæmaturia, epistaxis, hæmatemesis or uterine hæmorrhage may add to the gravity of the outlook.

The mere presence of blood-stained contents in the vesicles, especially those on the legs, without hæmorrhages into the bases of the pocks, or in the intervening skin and elsewhere, is not of bad prognostic importance.

Modified small-pox or varioloid.—Small-pox of a mild type may occur in vaccinated subjects although the same virus may prove virulent in those unprotected. In some, initial symptoms may be slight, and the eruption, although typical, is precocious and scanty. More commonly, the initial symptoms are severe, but again the rash appears early, is generally sparse and discrete, tends to evolve quickly, and many of its elements fail to progress beyond the papular or vesicular stage. The suppurative fever is slight or absent. The lesions of modified small-pox are often small, superficial and may be unilocular, sometimes they appear fleshy and wart-like. The modification is most evident on the face. The lack of depth and the arrest of maturation, leading to the juxtaposition of papules, vesicles and small pustules, may cause a resemblance to chicken-pox, or suggest measles complicated by chicken-pox, but the distribution remains characteristic although it may remain obscure in very sparse and abortive eruptions.

Rarely small-pox aborts completely in its initial stage, the focal rash failing to appear (*Variola sine variolis*). The subjects of this form of the disease have usually, but not invariably, been vaccinated at some previous time.

Variola minor.—A benign type of natural small-pox has from time to time prevailed in many parts of the world. The virus of this is sometimes known as the Western strain of the United States and West Indies in contradistinction to the Eastern strain or Asiatic small-pox. The names *alastrim*, *amaas*, *varioloid* *varicella*, and *Kaffir* or *Cuban itch* also designate this disease. It differs from ordinary small-pox in its mild course, low mortality (0.5 to 2 per cent.), lesser infectivity, the mildness or absence of secondary fever, the occurrence of residual pigmentation rather than pitting, and incidence on adults rather than on children.

The incubation period is 10 to 15 days, or longer. Invasion is abrupt, and may be accompanied by muscular pains, backache, vomiting and sometimes high fever, although many cases are ambulatory. The rash usually appears on the fourth or fifth day. It is seen first on the face, then on the forearms and trunk, and within 12 hours on the lower limbs. The eruption may be scanty or moderately profuse. It rarely comes out in crops, but in any case the initial lesions are more advanced than those which follow. Maturation is more rapid than in *variola major*, papular and vesicular stages each lasting 2 days, pustulation beginning early, and scabbing on the face being evident within a week. There is, as a rule, no secondary fever, but its absence is not invariable.

The distribution of the eruption is centrifugal, the rash favouring the face and extremities rather than the trunk. On the limbs, the distal parts and on the trunk the upper part of the back, rather than the abdomen and chest, are involved. Much weight is attributed to the detection of a few deep-seated lesions in the skin of the thenar and hypothenar eminences.

The lesions are more superficial than in *variola major*, but not so superficial as

the vesicles of chicken pox. They are not always spherical and are often unilocular and not umbilicated. Mature vesicles have an opalescent rather than frankly purulent appearance and the crusts are of a deep amber colour. It is easy to understand why the disease is so often mistaken for chicken pox. The distribution of the rash is the important diagnostic criterion. Although vaccination protects against variola minor the converse is not invariably true. As a rule vaccination in the eruptive stage fails but may take in modified form later.

Serological tests fail to differentiate variola minor from variola major.

Complications—During the later stages of small pox and in convalescence boils and superficial abscesses often cause trouble. Septic rashes and erysipelatous or impetiginous infections may spread from the pocks. The cervical and axillary lymph glands may in such cases become enlarged or even suppurate. In the more severe infections deep seated muscular abscesses, cellulitis or sloughing of the skin may occur and bed sores may form rapidly over pressure points. Rarely death is due to septicæmia arising from these secondary lesions.

Implication of the mucous membranes of the eyes, nasal cavities, fauces, larynx and gullet may bring its own train of serious complications. Ocular complications are important. Conjunctivitis is common. Pustules may form on the palpebral or ocular conjunctivæ. The eyelids often become inflamed and œdematous. A rapidly spreading keratitis may lead to sloughing of the cornea, but corneal ulcers are more common and sometimes lead to perforation and panophthalmitis. Irido cyclitis is rare. Retinal hæmorrhages sometimes cause blindness. The scars of the corneal ulcers may impair the sight.

Otitis media is comparatively common.

Laryngeal inflammation may be so severe as to necessitate tracheotomy and may lead to perichondritis and necrosis. Bronchitis and broncho pneumonia are frequent and often accelerate death, but lobar pneumonia and purulent pleurisy are rare. Endocarditis and pericarditis are also exceptional, but degenerative changes in the myocardium are not infrequent. Occasionally osteomyelitis or a destructive arthritis supervenes. Although albuminuria is often found, a frank nephritis is uncommon.

Parotitis is looked upon as a secondary duct infection from the mouth and secondary orchitis or oophoritis sometimes occurs during the acute stage.

As in other fevers encephalomyelitis and neuritis may occur some 5 to 13 days after the appearance of the rash, but the incidence of these is exceedingly low. On recovery from small pox speech may for a time be completely lost. Less favourable are bulbar or limb paralysis with or without derangement of sphincter control (see p 1411).

Deep pitting of the face, permanent blindness, deafness and sometimes alopecia may be the legacies of a severe attack.

Diagnosis—Papular or vesicular rashes which even though scanty affect the face and extremities symmetrically are always suspect. The body should be stripped and examined in a good light. A preliminary bath may be needed. Attention is first focused on the distribution rather than on the characters of the rash. The individual lesions should be plotted on an outline diagram of the body and a numerical comparison made of those on the abdomen, chest, back, shoulders and upper arms, forearms, face, buttocks, thighs and legs. Repeated observations will determine their spread and maturation. Too much reliance should not be placed on shottiness or umbilication. The condition as to vaccination should be ascertained and the nature of any prevailing epidemic borne in mind.

The initial fever may lead to the first difficulty in diagnosis, the symptoms of onset are very similar to those met with in other acute diseases, particularly influenza, acute rheumatism, pneumonia, typhus and cerebrospinal fever. Severe prostration and backache when present are suggestive. Often the diagnosis is not certain until the focal eruption appears on the third day and the fever subsides, but the appearance

of a petechial prodromal rash in the groins may lead to earlier recognition. It is more common for small-pox to be mistaken for influenza than for the converse to occur. Lumbar puncture is diagnostic in cerebrospinal fever. In pneumonia sooner or later lung signs appear. Precipitate certification of a supposed case of small-pox, even in a contact, is unwise, it is better to isolate and wait the appearance of the rash, remembering this should appear first on the forehead, near the roots of the hair, the cheek bones, sides of the nose, wrists, hands and forearms. The interior of the mouth should be inspected and also parts of the skin which have been subjected to special irritation.

The prodromal rashes, if purpuric, may be confused with different varieties of purpura or leukaemia, if erythematous, with scarlet fever, measles, rubella, urticaria or other forms of erythema

The characteristic groin or "bathing drawers" incidence of the purpuric rash of small pox is of great assistance in early diagnosis. More widespread purpuric rashes, however, are at times misdiagnosed as febrile purpura until the occurrence of small pox in contacts reveals their true nature. Conversely, febrile purpura and purpuric rashes occurring in bacterial endocarditis, cerebrospinal fever and other conditions may be mistakenly thought to indicate small-pox. The distribution of the rash and the character of accompanying symptoms should be noted. Physical examination of the organs may reveal signs which help to clear up the diagnosis, which may be very difficult.

A scarlatiniform prodromal rash is distinguished from scarlet fever by its explosive outbreak with the absence of tonsillitis and of punctate redness of the soft palate. The rash, too, on the skin is not definitely punctate and the area of circumoral pallor is wanting. The tongue is not typically nor are the tonsillar lymph glands enlarged. The Schultz-Charlton test is negative.

Morbilliform prodromal rashes are less common and bear only a very superficial resemblance to measles. The diagnosis is discussed below. Nor should rubella be confused if its characters are borne in mind. The prodromal erythema may resemble those induced by antitoxin serum by soap enemas and by drugs. The characters of these rashes are given in the article on scarlet fever (p. 45).

The focal eruption of small pox in its various stages may be confused with measles, chicken-pox, herpes zoster and even herpes febrilis or perhaps typhoid or typhus also with various forms of papular erythema, urticaria, icone, papular or pustular syphilides, and glanders. Sometimes drug rashes, particularly bullous eruptions due to iodides, lead to mistakes. Confluent or hemorrhagic small pox in the papular stage is often mistaken for measles. The 3 day prodromal fever and lesions in the mucous membrane of the mouth favour this error. But there is no real catarrh in small-pox, and the buccal infiltrations only superficially resemble Koplik's spots. The distribution of the rash and the fact the temperature tends to fall as the eruption increases instead of rising as it does in measles are distinctive.

The differentiation of chicken-pox is important. Chicken pox is a disease of childhood whilst small pox now chiefly affects adults, but cases of chicken pox in the adult are not infrequent, and in them prodromal symptoms may be sharp and the rash not appear until the second or third day. Chicken pox presents the following distinctive characters:

1 The rash of chicken pox appears first on the trunk, and is thickest on the trunk face, perhaps the scalp upper arms and thighs. It is centripetal and tends to avoid the extremities of the limbs. It does not so markedly select irritated areas, nor does it avoid the axillae and groins. The presence of many lesions on the palms and soles is greatly against chicken pox.

2. The eruption comes out in distinct crops for 3 to 5 days or more

3 The vesicles develop much more rapidly and are mature in 24 hours. Vesicles are not seen at this period in small-pox.

4. The lesions are superficial and unilocular, rarely umbilicated. Their bases are not indurated. Near flexures they may assume oval outlines, sometimes becoming irregular or crenated.

5. The outbreak of fresh vesicles on a given area of skin over a period from the 24th to the 72nd hour, i.e. on the second and third days, is characteristic. Hence by the third day the lesions of chicken-pox are in various stages of development from vesicles to crusts.

6. The lesions are smaller. Pustules and scabs half an inch across are almost certainly due to small-pox.

7. Efficient vaccination within 5 years or revaccination within 10 years is generally but not invariably evidence against the disease being small-pox.

8. Chicken-pox does not protect against successful vaccination in an unprotected individual: in small-pox vaccination will not take after the rash has appeared. This rule, however, is not absolute. Vaccination may prove successful in anomalous forms of small-pox, and has been alleged to take in ordinary small-pox on rare occasions.

9. Apathy and muscular relaxation are not features of chicken-pox. A copious rash with complete absence of prostration suggests chicken-pox rather than small-pox.

In distinguishing skin eruptions it should be remembered that zoster is rarely bilateral. Erythemas are often polymorphic; they may show occasional vesiculation which is quite superficial and are sometimes febrile. Acne affects the face, shoulders, back and chest, but not the forearms or hands; it is chronic, afebrile and often associated with comedones and scars. The lesions may be pustular but are never vesicular.

If syphilis is borne in mind its eruptions are not likely to be mistaken. Glanders is rare, but when the nodules on the face suppurate and are accompanied by fever, small-pox may be suggested. There is usually a nasal discharge and a history of close contact with horses. Bacteriological examination will show the *Pfeifferella mallei*.

Laboratory diagnosis.—Certain laboratory tests are valuable:

1. Detection of variola antigens in the vesicular fluid or in the crusts by a precipitation test or by complement deviation, making use of anti-vaccinal rabbit serum.

2. Paul's test which depends on the production of Guarnieri bodies by scarification of the cornea of a rabbit with vesicular fluid from small-pox or vaccinia.

3. The intradermal injection of vesicular fluid produces in the rabbit a characteristic inflammation which is prevented by previous admixture with hyperimmune rabbit serum.

4. The procedure recommended by van Rooyen and Illingworth who have shown that even in the early papular as well as in the vesicular stage of small-pox the elementary bodies can be demonstrated in great profusion by the application of Paschen's method of staining to films of scrapings from the bases of the buccal lesions, the skin papules and the vesicles, but not the pustules of small-pox. This facilitates early diagnosis. Moreover, since the elementary bodies of chicken-pox, herpes zoster and also of herpes febrilis are smaller, scantier and extremely difficult to stain, the important differentiation of these diseases is possible.

5. Inoculation of the chorio-allantoic membranes of a growing chick embryo with the virus of small-pox or vaccinia produces discrete plaques. These do not appear when the virus is that of chicken-pox. Febrile herpes and herpes zoster also produce visible lesions, which can be identified serologically.

Procedures 1 and 5 are the most valuable differential tests.

Prognosis.—Variola major has a mortality which varies from 25 to even 50 per cent. The prognosis may be considered under the following heads: (1) The vaccinal condition of the patient, (2) the age; (3) the nature of the attack; and (4) the character of the prevailing epidemic.

1. When a vaccinated person takes small-pox the nature of the attack usually

indicates some residual immunity, the severity of the disease being less and the mortality much lower than in the unvaccinated. The presence of large, well-foveated vaccination scars renders the prognosis very favourable. After the age of 15 or even 3 years earlier, the protective influence of infantile vaccination will to a large extent have disappeared, but revaccination at puberty, properly performed, confers a high degree of immunity for the rest of life.

2. In the unvaccinated the death-rate from variola major in the first 5 years of life is very high and may exceed 40 per cent. After that there is a fall, at first gradual, then considerable, up to the age of 15 or 20, which is the most favourable period. Subsequently the mortality rises steadily and may even exceed the figures given for the first quinquennium. In the vaccinated, however, the younger the patient the more certain is recovery. If revaccination has not been performed, as age increases the mortality does so also, and may reach 15 per cent. in persons over 30 years of age.

3. The nature of the symptoms is important. Mild invasion presages a mild attack. Severe invasive symptoms usually, but not invariably, mean a severe infection, but they may precede mild attacks in the vaccinated and sometimes in others. Prodromal rashes of a vivid lobster hue, especially if petechiæ are present, are the heralds of grave, often hæmorrhagic infections. Very intense backache is also an ominous invasive symptom. The more profuse the pustular rash the worse the prognosis, but the intensity of the suppurative stage is much modified by previous vaccination. Confluent eruptions mean a bad outlook, whilst patients in whom the rash remains discrete usually recover. Recovery from the vesicular or pustular form of hæmorrhagic small-pox is occasional, but in the pre-eruptive *purpura variolosa* death is usually inevitable. Bleeding from mucous membranes is of very bad augury.

Other unfavourable symptoms are incomplete remission between the primary and secondary fever, sleeplessness, active delirium, especially in drinkers, considerable implication of the larynx and broncho-pneumonia. The influence of pregnancy in inducing abortion and miscarriage has already been mentioned (p. 159).

4. Epidemics vary much in their severity and mortality. In some the disease is so slight and the mortality so low, that doubts arise whether the epidemic is really small-pox.

Treatment.—**PROPHYLACTIC.**—Vaccination and revaccination are the most powerful safeguards. The chief measures to be taken when the disease is recognised are the following: (1) Prompt removal of the patient to an isolation hospital. (2) Thorough disinfection of infected rooms and clothing. (3) Immediate and efficient vaccination or revaccination of all other members of the household and of contacts. Four or even more days after exposure vaccination may prove effectual in preventing the disease, at all events will modify it (see p. 163). (4) Quarantining of contacts for 16 days, or a daily inspection so that initial symptoms may be detected at once. (5) Notification of schools or institutions attended by inmates of the same house.

Inoculation with small-pox, which confers more complete immunity than vaccination and which prior to vaccination was a method of prophylaxis, is said in some instances to have a mortality of 2 or 3 per cent.; but even this compares favourably with a mortality of 40 or 50 per cent. as seen in some epidemics of ordinary small-pox. Inoculation, however, was found to spread the disease, and so has, in England, been made a penal offence.

SYMPTOMATIC.—Fresh air, cool surroundings, light bedclothes, free fluid intake, regulation of the bowels and tepid sponging night and morning form the regular routine. The mouth should be cleansed regularly, and the nose gently douched or liquid paraffin instilled. Pain in the head and back may be mitigated by the ice-bag to the scalp and use of fomentations to the loins. Aspirin, phenacetin or chloral and bromide may give relief; but the drug most generally useful, both in this stage and in the sleeplessness, delirium and discomfort of the secondary fever, is opium in the form of gr. 10 of Dover's powder. Sometimes paraldehyde is effectual. Delirious

patients should never be left alone. The vomiting of the early stage is allayed by citrating the milk or substituting ice and champagne. Liquor iodi mitis in 5-minim doses is also useful. When fever continues high and is accompanied by toxæmia and delirium, tepid sponging may be replaced by hot or cold packs with advantage.

Many methods have been tried in the hope of aborting the eruption and preventing the subsequent sepsis and pitting. Sulphonamides have no influence on the toxic stage, but both they and the antibiotics are said to influence favourably the focal eruption in the vesicular stage and to be of value in the septic complications. Some advocate painting the face with liquor iodi mitis, diluted if painful, twice a day for the first 8 or 10 days, and then applying soft paraffin, or, better, commencing in the papular stage, a saturated (5 per cent.) solution of potassium permanganate may be painted over the whole body three times a day until scabbing begins, and afterwards less frequently. In confluent cases the patient may be immersed daily in a 3 per cent. permanganate bath for 15 minutes at body temperature. The application of a lint mask soaked in glycerin is useful, and glycerin may also be applied to the hands. It may be necessary to cut the hair short. To mitigate the offensive odour, dilute carbolic lotions may be applied (they also relieve the itching), or creosote may be vaporised in the sick room. Starch poultices and alkaline washes are used for the removal of crusts and zinc ointment or a 5 per cent. sulphathiazole ointment with 1 per cent. of phenol applied.

The eyes should be bathed with boric acid lotion at frequent intervals, and dilute nitrate of mercury ointment smeared on the edges of the lids. Should keratitis threaten silver protein is instilled or an ointment of atropine with yellow oxide of mercury applied.

Laryngitis is relieved by a steam tent and inhalations of benzoin or lysol.

Patients are to be regarded as infectious until the scabs are all separated and the skin and mucous membranes quite healed. Deep seated crusts in thick skin should be extracted and destroyed.

VACCINIA

Vaccinia or cow pox a disease at one time very prevalent among cows, but now rare is characterised by a vesicular eruption on the udders and teats. The vesicles which are surrounded by inflammatory areolæ, may by rupture form extensive ulcers. Abrasions on the hands of milkers may be accidentally inoculated from these lesions and they, in turn, may inoculate other cows in the herd. The hands of the infected milkers show vesicles with surrounding induration, the axillary glands become swollen and there is some fever.

Individuals accidentally inoculated with cow pox are protected from small pox, and Edward Jenner made practical use of this fact by inculcating the practice of deliberate vaccination and transference of the virus from arm to arm. In addition he demonstrated that those thus vaccinated were refractory to subsequent inoculation with the virus from small pox lesions, and that milkers who had had small pox did not catch vaccinia from the cows. But it appears that although vaccinia protects against small pox an attack of small pox does not invariably protect against vaccinia.

After long dispute, the question of the identity of cow pox and small pox has been settled by animal experiment in favour of Jenner's view that the two diseases are one and the same, small pox virus being so modified by its transmission through the cow that its inoculation results only in a local lesion, a lesion which, however affords a high degree of protection against small pox. Vaccinia differs from small pox, whether the latter is natural or deliberately inoculated, in that it has lost its infective character, and so can be used for purposes of vaccination without risk of propagating small pox.

The histology of the vaccine vesicle is similar to that of the lesion of small pox. It goes through the stages of papule, vesicle and pustule, and loculation is produced by persistence of the remnants of vacuolated epithelial cells in the form of septa.

Professor Paschen has described minute "elementary bodies" as constant accompaniments of vaccinal lesions, and Ledingham has shown that these "Paschen bodies" are agglutinated by the sera of rabbits which have recovered from vaccinia. It is believed that these bodies are the filtrable virus of the disease.

For the purpose of vaccination vaccine lymph is prepared by the inoculation of healthy calves, the contents of the vesicles being collected and freed from pyogenic and other extraneous organisms by admixture with glycerin. This process of glycerinisation kills most of the adventitious germs, but leaves the virus of vaccinia uninjured. The lymph thus prepared, if stored in capillary tubes at low temperature, will remain efficacious for at least 8 months. Vaccinia virus may be cultivated on the chorio-allantoic membrane of chick embryos and this product has been used for vaccination. Continuous passage deprives the virus of some of its virulence, and there is good evidence that it affords less enduring protection against small pox than calf lymph.

Vaccination is carried out as follows. An area of skin over the insertion of the left deltoid muscle or on the outer side of the thigh or leg is cleaned with soap and water, and afterwards with ether or acetone and allowed to dry thoroughly. A drop of lymph is ejected from the capillary tube on to the area of cleaned skin and, with a sterile needle, a scratch is made through it one quarter of an inch long and just deep enough to penetrate the epidermis without drawing blood. The arm should be left uncovered until the lymph has dried and a wheal appeared when a sterile dry dressing should be applied.

Until 1929 it was customary to make four insertions of lymph but, following an increase in post vaccinal encephalitis, a Vaccination Order of that date recommended a single linear insertion of the type described. In 1947 the Ministry of Health advised a single insertion for primary vaccination in infants and two insertions an inch apart for others. Revaccination should be effected by one insertion. It is probable that this method does not provide immunity for more than 1 or 2 years and it should be repeated yearly in those especially exposed to infection.

If the operation is successful, inflamed areas appear at the sites of inoculation, and by the third day become distinctly papular and itchy. By the fifth day, small clear vesicles have formed which slowly increase in size and become depressed at their centres. By the eighth day the vesicles are large, sharply defined and their inflammatory areolae are confluent. From this time the contents become increasingly cloudy. The vesicles attain their full size by the twelfth day and collapse. By the tenth or twelfth day a brownish scab is forming. This separates later, leaving a depressed and pitted or foveated scar which at first is livid, but in course of time becomes dull white.

An alternative method which is very effective is vaccination by multiple pressure. In this a flat sided needle held between thumb and forefinger is laid tangentially on the skin its point in a drop of lymph. By finger pressure on its shaft it is rapidly depressed and released 20 times or more. By this means the epidermis is pierced superficially by the side of the needle point without drawing blood.

In vaccination the virus is distributed by the blood throughout the body. Head-ache, malaise and fever accompany maturation of the vesicles at the beginning of the second week, the axillary glands may become enlarged and tender and the spleen palpable. Sometimes febrile disturbance is noticed as early as the fourth day.

In revaccination the events are similar, but both the local and constitutional disturbances are accelerated and less pronounced or may fail to appear. The lesions may run a very rapid course aborting at the papular or early vesicular stage. Vaccination should only be recorded as successful when a vesicle appears. A fleeting papule 8 to 72 hours after vaccination is often a sensitivity reaction to some alien constituent.

of the lymph. The Ministry of Health (1947) has recommended that the results of vaccination should be recorded as follows: negative—"No local reaction to vaccination (repeated)"; erythema only—"Maximum local reaction (non-vesicular) on second to third day"; vesicular (maximum 3 to 7 days)—"Accelerated or vaccinoid reaction"; marked vesicular (maximum after seventh day)—"Typical vaccinia, primary or equivalent".

Natural insusceptibility to primary vaccination is excessively rare, and at least three successive attempts should be made before insusceptibility is assumed.

Although infants can be vaccinated successfully in the first few weeks of life, under ordinary circumstances the best period is from the second to the sixth month. Revaccination is advisable after the second year and when small-pox is epidemic. Vaccination is no longer obligatory in Great Britain.

The degree of protection afforded is in some degree proportional to the extent of the vaccinal lesion. The test of a successful scar is its depression and foveation, the latter indicating that vesiculation has occurred. The period of immunity may be regarded as not less than 2 years.

RISKS OF VACCINATION.—Fugitive erythemata, which are sometimes scarlatiform, mealy or urticarial, may appear about a week after vaccination; they are akin to serum rashes. Erysipelas, septic infection and cellulitis sometimes result from the use of contaminated lymph or the lack of proper cleanliness at the operation or after. Under modern methods of glycerinisation and asepsis, these should not occur. There is no doubt, too, that syphilis has on rare occasions been conveyed by arm-to-arm vaccination. In such cases, the chancre does not appear before the fifteenth day, and is usually later. The calf being insusceptible to syphilis, the use of calf lymph has abolished this danger. Tetanus is another infection which has occasionally resulted, especially in hot climates. Tuberculosis and leprosy have also been cited as possible sequels, but with little or no proof. The appearance of eczema and impetigo has been attributed to vaccination.

A rare sequel, to which special attention has been drawn, is a form of encephalomyelitis. Its greatest incidence has been in Holland, Great Britain and Germany, and has varied from 1 in 5000 to 1 in 100,000 vaccinations. The characteristic lesion is a focal, perivascular demyelination of nerve fibres, often associated with perivascular cuffing. It very rarely follows vaccination during the first year of life. Its chief incidence is where infantile vaccination is not the rule, i.e. after primary vaccination of children of school age or of adolescents. Very similar to the encephalomyelitis of small-pox and of measles, it sets in 7 to 12 days after vaccination, with headache, vomiting and paresis. These symptoms become aggravated, and delirium may pass into coma and death. In other cases the symptoms are more suggestive of meningitis, myelitis, lethargic encephalitis, with ocular palsies or of tetanus. The mortality may reach 50 per cent., but when recovery occurs it is usually complete. Human serum, from a healthy donor who has been successfully vaccinated recently, or anti-vaccinal horse-serum, is the best antidote. The serum is given intravenously. The dose is 8 to 30 ml., repeated if necessary. Repeated lumbar puncture is a valuable adjuvant.

Latent infection may be brought into activity and prominence by vaccination; this is the case with congenital syphilis and tuberculosis. Hence the advisability of postponing vaccination until the age of 2 or 3 months or should the infant show skin eruptions or signs of ill-health. Acute specific fevers are no bar to vaccination if necessary.

Very rarely the course of vaccinia is complicated by the appearance of a generalised vesicular eruption, the lesions appearing on the trunk and perhaps in successive crops. They pass through the stages of papule, umbilicated vesicle and crust. Generalised vaccinia of this type is usually febrile and occurs from 7 to 11 days after vaccination.

Accidental vaccinia is the term applied to fortuitous inoculation from a vaccinal

lesion Mothers are sometimes thus inoculated from their infants, the common site being the face, lip or eye The mouth, throat or a skin lesion may at times be involved When occurring on the face, there is much œdema with swelling of the lymph glands, so that anthrax or syphilis has been suspected The vaccinated baby may also, by scratching, inoculate its own nose, cheeks, fingers or other parts of its body

PROTECTION AFFORDED BY VACCINATION—The immunity to small pox which vaccination confers is not necessarily permanent Ten years is considered an average duration A child vaccinated in infancy should be revaccinated at the age of 7 years and again in adult life In areas where small-pox is endemic revaccination every 10 or 12 months has been recommended Whatever their vaccinal condition, persons coming into contact with small pox should be revaccinated at once

Since vaccinia has a shorter incubation period than small-pox, a person efficiently vaccinated or revaccinated within 3 days of exposure to the latter disease will, in all probability, escape it, but vaccination does not fully protect during the first week of the vaccinal period should exposure continue Ricketts made the following statement "The period of incubation of small pox, counting to the outcrop of the rash, may be taken as 14 days If this period be divided into three intervals comprising 7 days, 3 days and 4 days, it will be accurate, in the main, to say that a successful vaccination done in the first period will wholly prevent the attack, done in the second will have more or less effect in modifying the eruption, and done in the third will merely add to the patient's troubles "

CHICKEN POX

Synonyms—Varicella, Glass pock, Water-pock

Definition—An acute infective disease, characterised by a rash which tends to appear in successive crops, each lesion passing rapidly through a papular stage to one of superficial vesiculation and subsequent partial pustulation The lesions then desiccate and scab

Ætiology—Chicken pox is universally prevalent and highly infectious One attack usually affords complete protection, second attacks being extremely rare It is mainly an affection of middle childhood, being uncommon after 10 years of age, but adults even of advanced years may contract it, and infants are not completely immune Season and climate are not known to exert any influence on its incidence It affects both sexes equally Infection is in most cases direct by droplet spray, but articles of clothing may remain infectious for a considerable time, and the disease is sometimes carried by a healthy intermediary The dried scabs can communicate the disease, probably by powdering and ingestion or inhalation Like small pox, chicken pox is inoculable from the vesicles—but not easily Convalescents from acute diseases, particularly from measles, diphtheria and scarlet fever, are believed to be peculiarly susceptible to chicken pox The disease occurs sporadically or in the form of limited outbreaks The infective agent is a virus, and the association with herpes zoster lends support to the view that it may be a filtrable virus, identical with the neurotropic virus of that disease

Pathology—Micro organisms occur in the pocks, and particulate bodies have been described similar to those seen in vaccinia and small pox Pure suspensions of these particulate or elementary bodies are agglutinated by the serum of convalescents from varicella or herpes zoster The inflammatory lesions are more superficially situated in the skin than those of small-pox, but the process of vesiculation is similar Loculation is indistinct, and umbilication exceptional When the clear vesicles become clouded, but rarely before this, polynuclear and mononuclear cells are found in their contents An occasional leucocytosis and a shift to the left occurs in the first week Later eosinophils, plasma cells and Turk cells also appear

Symptoms.—Incubation period—This is usually a fortnight or a little more; but extremes of 11 to 23 days are mentioned.

In childhood the appearance of the eruption usually constitutes the first sign, and is taken to indicate the first day of the disease. In adults slight pyrexia and sometimes headache, shivering and even pain in the back may precede the eruption for 48 hours. In exceptional cases, mostly in children, vomiting and convulsions have occurred at the onset.

Prodromal rashes are not very uncommon. An erythema, either patchy or uniform, which may be punctate, sometimes precedes the eruption for some hours and may be mistaken for scarlet fever; it avoids the face, does not blanch by the Schultz-Charlton test and does not desquamate. The incipient papules of chicken-pox can sometimes be recognised in the erythema or in the mouth. Less frequently the prodromal rashes are measly or urticarial.

The eruption of chicken-pox appears first on the trunk, but soon spreads to the face, the scalp and the proximal parts of the limbs. Sometimes it is on the face that it is first noticed. Occasionally, and it may be primarily, the eruption invades the mucous membranes, especially the fauces, soft palate and the pharynx. The lesions have been seen in the alimentary canal, the bladder and the renal pelvis, also on the peritoneum. The spread of the rash does not conform to the orderly progress of small-pox, it appears in several crops on successive days; these may come out for 2 or 3 days in mild cases, for a week or more in those which are severe. The total number of lesions may be anything from a few to some hundreds. They are thickest on the trunk, especially on the back, and next to this on the face and in the scalp. They tend to invade the limbs from above downwards, but are characteristically sparse and often small on the distal portions, a few vesicles are occasionally seen on the palms and soles. The axillæ do not escape as in small-pox, and it is unusual for the rash to show an especial incidence over ridges or pressure points. Various forms of skin irritation may, however, at times determine a local profusion of the rash.

The lesions are in turn macular, papular, vesicular and mildly pustular. The macules are very transitory, soon becoming rounded or ovoid papules of a pinkish colour and slightly salient, something like the rose spots of typhoid, or larger. Vesiculation rapidly ensues, and is complete in 24 hours or a little more. The vesicles seldom exceed a third of an inch in diameter. They look like translucent droplets, lying on rather than in the skin. An areola may or may not be present. On the scalp, forehead, hands and feet they may be set deeper, and show some hardness. Some assume oval or irregular outlines, especially when lying near creases or folds of the skin. On maturity the vesicles take on a pearly hue. When punctured, most of them collapse entirely, and umbilication is rare. Confluence of adjacent vesicles hardly ever occurs. Owing to its itchiness, the rash is often infected by scratching or rubbing, and then the lesions become larger and more inflamed. Otherwise the vesicles dry up into superficial brown scabs in a day or two, which on separating leave slight pink

the adult. There are three special but uncommon varieties of the disease (1) *Varicella bullosa*, (2) *Varicella gangrenosa* and (3) *Varicella hæmorrhagica*. In *V. bullosa* the vesicles rapidly form large blebs, which on rupture leave painful raw surfaces. *V. gangrenosa* is seen in debilitated children and those recovering from scarlet fever, large dark crusts form and on separation reveal ulcers which may spread on the surface and in depth with great rapidity. Constitutional disturbance is severe, and pulmonary complications often supervene. Infection of the lesions with yellow staphylococci, hæmolytic streptococci or virulent strains of the diphtheria bacillus should be suspected. *V. hæmorrhagica* is rare, hæmorrhages occur into the vesicles and intervening skin, and bleeding sets in from the mucous membranes. It has a very high fatality rate. Bleeding confined to the vesicles is not so serious.

Complications.—Laryngitis or slight bronchitis is present in some cases. Pocks on the conjunctivæ, vulva or prepuce may give rise to troublesome symptoms. Accidental septic infections sometimes occur in the eruptive stage. Acute nephritis and arthritis are exceptional results of these.

Nervous complications are very rare and usually benign. They are attributed to encephalomyelitis, and chiefly affect children usually occurring during the second week of the infection. Rarely they precede the eruption. The onset is acute and febrile, it may be accompanied by vomiting, vertigo and convulsion. Ataxia and tremor are more common than motor paralysis. With spinal lesions the picture may be that of a transverse myelitis. Optic neuritis, ophthalmoplegia and, very rarely, peripheral neuritis have also been recorded. In most cases recovery has ensued.

Herpes zoster is closely akin to chicken pox. A scattered vesicular rash indistinguishable from chicken pox may precede, accompany or follow the zoster eruption. Herpes zoster may also give rise in contacts, mostly children, to typical chicken pox after an incubation period of from 12 to 21 days, and chicken pox may follow inoculations from zoster vesicles. The converse, for chicken pox to give rise to herpes zoster, is a much less common event, which usually occurs in adults. It is a curious fact that there is no clinical evidence of any cross protection between the two diseases.

Diagnosis.—A mild or modified case of small pox may erroneously be supposed to be chicken pox or chicken pox with a profuse eruption and constitutional or the rare hæmorrhagic symptoms may be supposed to be small pox. The differential diagnosis, in which the distribution of the rash is of primary importance, is considered in the article on small pox. Here it may be stated that in a patient under 10 years of age, with well foveated vaccination scars a profuse eruption is generally chicken-pox, whilst a scanty eruption with well marked invasive symptoms is more likely in these circumstances to be modified small pox.

The erythematous prodromal rash may simulate scarlet fever, but other signs of this disease are wanting, and the chicken pox eruption appears within 24 hours in the mouth or on the skin (see also p. 45).

Certain skin diseases characterised by vesicles or bullæ may be mistaken for chicken pox. These include insect bites, scabies, acne impetigo, papular urticaria, pemphigus and erythema multiforme. Differential criteria are prolonged duration, recurrences, distribution, absence of fever and usually no lesions in the mouth.

A varicella like type of syphilide is known. It usually affects the trunk, is much more persistent and is accompanied by other evidence of its nature.

Prognosis.—Death is very rare. The gangrenous form may prove fatal to debilitated children and the rare hæmorrhagic form is said by most authorities to have a very bad prognosis.

Treatment.—Although most infectious in the pre eruptive and early eruptive stages, patients should be isolated until every scab has separated—usually a period of 2 or 3 weeks. They should be confined to bed during the eruptive period. Skin irritation may be allayed by mild dusting powders, and it is sometimes advisable to fix the arms in light splints. It is rarely necessary to cut off the hair. Inflamed

pocks may need fomentation with boric acid. Crusts which re-form may be removed by starch poultices and zinc or mercurial ointment applied. Septic or gangrenous varicella is an indication for the use of an appropriate antibiotic, perhaps combined with a sulphonamide.

When discharging patients, particular attention should be paid to the scalp, as scabs may remain entangled in the hair. It is doubtful if lesions which have crusted several times are still infectious. The quarantine period for contacts is 3 weeks, but it is quite safe for it to commence 10 days after exposure to infection and be maintained for 12 days.

Attempts at prophylaxis with convalescent serum and gamma globulin have not proved very successful.

MUMPS

Synonyms — Epidemic Parotitis, Infectious Parotitis

Definition — An acute infectious disease, characterised by swelling of the parotid, and sometimes of the other salivary glands, accompanied by constitutional disturbance which is usually mild. With the exception of orchitis, complications are infrequent, and a fatal termination is exceedingly rare.

Etiology — Mumps is endemic in most large centres of population throughout the civilised world. No climate is adverse and no race is immune. Children and young adults of both sexes are those usually attacked, but no age is entirely exempt, although the disease is rare in infants and in the aged. The mother has transmitted the disease to the fetus *in utero*. There is also some evidence that congenital malformations may result. Dogs and cats have been known to contract the infection from their owners.

The malady usually appears during the winter or spring months. Outbreaks are generally localised, and often limited to particular schools, business houses or barracks. Infection is direct from patient to patient and close contact is necessary, but is sometimes conveyed by an apparently healthy intermediary, or by fomites.

Pathology — Mumps is due to infection by a neurotropic filtrable virus. Invasion of the nervous system is thought by some to occur prior to invasion of the salivary glands. An alternative view is that a primary septicæmia is followed by localisation of the virus in certain susceptible organs. The infection can be passed to monkeys by bacteria free filtrates of saliva on the first or second day of the disease, or by puncture fluid from the swollen glands, and has been re-transferred from monkey to man. The virus can be cultivated in chick embryos and the antigen from this source

ates the sulcus between the mandible and the mastoid process, lifts the lobe of the ear away from the head in a characteristic manner and extends forwards on the surface of the masseter. Only rarely is the skin over and around the gland either reddened or œdematous. The swelling subsides after a few days, sometimes very quickly, but a distinctive and, when present, highly diagnostic feature is the occurrence, 24 or 36 hours after onset, of swelling in the other parotid region, sometimes with fresh febrile disturbance; or the submandibular and sublingual glands may now be attacked. The interval between the invasion of the two parotid glands may extend to 4 or 5 days, or even longer; sometimes they are attacked simultaneously. Sometimes, too, the submandibular or sublingual glands become swollen first, in which case palpation with one finger in the mouth and another below the jaw will reveal the acorn-like swelling, and movement of the tongue may become painful. The parotid may escape, or may swell in its turn. The lacrimal gland is rarely attacked. When multiple bilateral glandular swellings are present the features become much distorted.

Moderate pyrexia (101° or 102° F.) may accompany the onset and persist for a day or two; but the attack is often afebrile and the pulse-rate hardly quickened. On rare occasions constitutional disturbance is severe, the temperature rising to 104° or 105° F., with delirium and circulatory depression. It is said that the spleen usually becomes palpable.

The glandular swellings are accompanied by a feeling of tension rather than acute pain, but the inflamed parotid gland may cause great pain on attempts to separate the teeth, to chew or to swallow. The secretion of saliva is often defective, but in some excessive salivation is noticeable and food may increase the swelling of the gland. Injection of the orifices of the salivary ducts, pharyngitis and even tonsillitis are sometimes observed at the height of the attack. Enlargement of the cervical lymph glands may occur.

Mumps may appear in so mild a form as to be hardly noticeable. At times the only gland affected is the submandibular (*Submaxillary Mumps*). Occasionally orchitis, pancreatitis or lymphocytic meningitis is the sole manifestation of the disease.

With rare exceptions the swellings caused by mumps neither suppurate nor persist, although, occasionally, the parotid gland is said to be several months in resolving. Relapse sometimes occurs.

During the period of glandular swelling the blood usually shows a moderate leucocytosis, a characteristic feature being a relative and absolute increase in the number of lymphocytes. The supervention of orchitis does not invariably alter the blood picture, although, according to some authorities, it may give rise to an increase in the number of polymorphonuclear cells.

Complications.—*Orchitis* occurs in 15 to 30 per cent. of the males. It affects boys about the age of puberty and young adults; in childhood it is rare. Sexual activity is held to be a definite predisposing factor. The seventh or eighth day of illness is the usual time of onset; but it may occur 2 or 3 weeks later. In some instances orchitis precedes the inflammation of the salivary glands. The condition is really an epididymo-orchitis. Where surgical attempts have been made to relieve tension by decapsulation or incision of the tunica albuginea, effusion has been found in the tunica vaginalis, the testis engorged and the epididymis deep red. The onset is characterised by pain in the testis, which soon becomes swollen. Delirium, vomiting, collapse and considerable fever may accompany the testicular inflammation. The temperature may rise abruptly to 103° or 104° F. Fortunately the complication is usually one-sided, but in 10 to 20 per cent. of cases the other testicle is attacked in turn. Orchitis may be accompanied by œdema of the scrotum, swelling of the spermatic cord and enlargement of the inguinal glands. The pain may radiate to the lower abdomen. Exceptionally urethritis accompanies the testicular swelling. Subsidence of orchitis within a week is the rule, the temperature falling rather abruptly. Suppuration is very rare; but relapse sometimes occurs. Less than half the cases

show some appreciable testicular atrophy. When bilateral orchitis occurs before puberty the development of the individual is usually checked, rarely feminism has been reported. In the adult, even when as a sequel both testes appear atrophic, spermatogenesis may return after many months.

In the female, oophoritis, inflammation and œdema of the vulva and mastitis are occasional complications.

Pancreatitis is a much less common complication than orchitis, but like the latter on rare occasions is the only manifestation of mumps. It should be suspected when acute abdominal pain, fever, vomiting and epigastric tenderness occur as sequels to the parotid swelling, which under these circumstances may show a rapid subsidence. Sometimes the swollen pancreas may be felt, but often its presence is masked by abdominal rigidity. The bowels are constipated, the stools may be fatty, or even contain blood. The serum and the urinary diastase is increased, as also is the lipase. The blood sugar may be raised, and glycosuria may occur. Jaundice is rare. The onset may be accompanied by alarming collapse. Fortunately recovery has occurred in most cases. Diabetes as a sequel to mumps is very exceptional, but undoubtedly may occur, sometimes even when the abdominal symptoms have been quite trivial. When mumps attacks a diabetic dangerous ketosis may occur. It should be noted that in mumps a raised diastatic index may occur without clinical evidence of pancreatitis, and is then attributed to infection of salivary glands.

Nervous complications are exceptional. Meningismus may signalise the onset and meningo-encephalitis may set in towards the end of the first or during the second week, it has even been known to precede the appearance of the glandular swellings. Later and rarely, an ascending paralysis or a general paralysis of the limbs and of certain cranial nerves, attributed to peripheral neuritis, occurs. As a general rule, however, a parotid swelling which causes unilateral facial paralysis is not due to mumps.

An excess of lymphocytes or of protein may be found in the cerebrospinal fluid, and is not uncommon during the first 15 days of mumps, even in the absence of definite meningeal symptoms.

Certain affections of the *organs of special sense*, although uncommon, deserve mention on account of their importance. Quite apart from deafness, due to the occasional occurrence of otitis media, true nerve deafness may occur unaccompanied by signs of middle ear disease. The deafness is of sudden onset, and when accompanied by nausea, vomiting, tinnitus and inco-ordination it is attributed to hæmorrhage or exudation within the labyrinth, but it may occur without any labyrinthine symptoms. Fortunately the deafness is usually unilateral for it is incurable. A few cases of deaf-mutism have been attributed to mumps.

Papilloedema or retro bulbar neuritis and optic atrophy are other rare but important sequels. Indocyclitis, paralysis of certain extra ocular muscles and loss of power of accommodation may also at times ensue, these mainly terminate in recovery after a variable time.

Among other possible complications may be mentioned epistaxis, bronchitis, pneumonia, pericarditis and arthritis. Electrocardiographic evidence of myocarditis has been reported in as high a proportion as 15 per cent in some series. Transitory albuminuria is not uncommon and nephritis sometimes occurs as late as 4 or 5 weeks after the onset of the salivary swellings, uræmia has been responsible for death in rare instances.

Suppuration in the parotid gland, gangrene of the gland, cellulitis of the neck and floor of the mouth and suppuration of the cervical lymph glands are very rare events, which are generally attributed to superadded septic infection. The inflammatory œdema of submaxillary mumps has on occasions spread to the glottis and necessitated tracheotomy. It has been noted, too, to affect the tissues overlying the manubrium sterni.

Relapses, characterised by a recurrence of the glandular swelling after a distinct interval, are not very uncommon. Although one attack of mumps usually protects the individual for life, second attacks are not unknown.

Diagnosis—In the presence of an epidemic this presents little difficulty, but the true nature of the infection may be overlooked in sporadic cases or when the parotid swelling is insignificant, and when the disease primarily affects the submandibular or sublingual glands, or again when orchitis, pancreatitis or even meningoencephalitis constitutes the first, and perhaps the only, manifestation.

Parotitis, usually unilateral, and attributed to ascending duct infection, is a well-known complication of certain fevers and of some abdominal diseases. This is not contagious. It generally ends in suppuration, and is accompanied by a polynuclear leucocytosis. Swellings of the salivary glands, distinguished from mumps by their recurrent nature, are attributed by some to a mild chronic infection of the ducts, which may be dilated, others believe them to be allergic in nature (see p 532). Swelling of the salivary glands may also follow the administration of certain drugs, such as iodide of potassium and pilocarpine, or be caused by salivary calculi.

A painless enlargement of the parotid and lacrimal glands of great chronicity, occurs in Mikulicz's disease. In vesicular parotid fever irido cyclitis accompanies the parotid swelling (see p 532).

Inflammatory swelling of the higher cervical glands, especially when accompanied by periaadenitis and oedema, may be mistaken for mumps. Swelling of this character occurs in certain cases of malignant diphtheria and also in scarlet fever. Careful attention to the history, proper examination of the fauces and search for rashes should eliminate this serious error. Enlargement of the preauricular lymph gland due to lesions about the nostrils and angle of the mouth, and the swelling caused by peristitis of the lower jaw, or otitic infection of a zygomatic air cell, may superficially resemble inflammation of the parotid, as also in some cases may subcutaneous emphysema.

When the submandibular and sublingual glands alone are swollen the distinction from lymphadenitis may be difficult. In such cases extension to the opposite side indicates mumps as also does the transitory character of the swelling. In all forms of septic adenitis a polynuclear leucocytosis is likely to be present.

In glandular fever, which is an acute infective adenitis of the cervical and other lymphatic glands, the salivary glands are not involved.

Prognosis—The mortality from mumps is remarkably low. Most deaths occur in children under 5, especially in infants, usually from some complication. Attacks of mumps in pregnancy have been known to prove fatal, and on rare occasions congenital malformations have been attributed to them.

Treatment—Mumps is infectious for 2 or 3 days before the swelling appears, after that infectivity rapidly becomes negligible. Isolation for not less than 2 weeks from the onset is advisable, provided that 1 clear week has elapsed since the subsidence of the glandular enlargement. Some would reduce the week to 3 days. Contacts should be removed from exposure and isolated for 28 days or better, supervised from the fourteenth to the twenty eighth day, unless they have already had the disease. Thirty ml of whole blood, or 15 ml of serum of recent convalescents, if given on first exposure, seems to prevent infection, but its protective effect only lasts about 14 days. A fractionated globulin has also been prepared. Attenuated attacks are difficult to produce, but see also remarks under measles (p 154). On account of the liability to orchitis it is better to have mumps before puberty than after. Gamma globulin from recent convalescents has given the best results in preventing this complication. In fulminant and bilateral attacks incision of the tunica albuginea has been found to relieve pain and fever, and thought to avert subsequent atrophy. For the after results substitution therapy with testosterone may be considered.

The patient should be isolated and confined to bed. The incidence and severity of orchitis are said to be less in those who are not allowed to get up until the time at which this complication usually appears is past. Foods which need no mastication are indicated during the acute stage. The mouth should be kept clean. Pain may be relieved by local applications and acetylsalicylic acid. The inflamed testicle should be enveloped in cotton-wool and suspended or supported by a small pillow. If pancreatitis is suspected, fomentations may be applied to the abdomen, small doses of opium administered and the diet strictly restricted to fluids. Delirium and pyrexia are met by sponging, wet-packs or the ice-cap. Hyoscine may become necessary. Repeated lumbar puncture is beneficial in meningo-encephalitis.

INFLUENZA

Definition.—An acute infectious disease of short duration, existing in pandemic and epidemic form, with sporadic outbreaks. It is characterised by sudden onset, pyrexia, headache, pains in the back and limbs, and a tendency to inflammatory complications in the respiratory system.

Ætiology.—There are influenzas rather than influenza, but there are questions which have baffled epidemiologists and bacteriologists for many years, nor did the exceptional opportunities for observation and research afforded by the pandemic of 1918-1919 serve entirely to answer them. Are the protean features of disease which are at present included in our conception of influenza all manifestations of the same *materies morbi*? What causative factors determine the pandemics of the disease during which the case-incidences rises so rapidly and so enormously? What is the association between benign influenzal catarrhs of endemic and sporadic occurrence and the pandemics which decimate whole races of mankind?

We are ignorant of the reasons why a state of relative quiescence in regard to the incidence of the disease—scattered sporadic cases and mild epidemics—suddenly blazes up into a devastating pandemic. We know that when this conflagration arrives the disease becomes very highly infectious in character, that its virulence is enormously increased and that the usual close association with catarrhs and seasons and latitudes and lowered general resistance is no longer observed. Age gives no security at such times, witness both the high case-incidence and high case-mortality in young adults during the pandemic of 1918-1919.

A previous attack of the disease gives little or no protection, according to some authorities the reverse is the case, yet promising results from prophylactic virus vaccine inoculation have been reported.

In the matter of its relation to other catarrhal states the absence of definite criteria makes it impossible to be precise in diagnosis. It is only in the presence of a severe and widespread outbreak that the guide of probability is of assistance in this respect.

Andrewes and his co-workers at the National Institute for Medical Research in 1933 isolated from the naso-pharyngeal discharge of influenza patients a virus which is capable of infecting ferrets. When human influenzal garglings are dropped into the noses of ferrets they become ill in 48 hours and the disease has been transferred from the experimental animals to the experimenter. Further, they have shown that patients who have had influenza recently develop antibodies in their blood which kill, or inactivate, the virus. Neutralisation tests with antisera prepared from human strains prove that different serological varieties of the virus exists. So far virus A and virus B have been identified, each with different epidemiological behaviour, but there are cases which, though clinically influenza, are not due to either of these, and in which no recognised virus or antibody can be demonstrated. Such cases have provisionally been designated "influenza Y".

Virus A appears to be associated with most of the more widespread and virulent epidemics, but no hard-and-fast distinction is possible. Virus B influenza is commonly sporadic, mild and of insidious onset, but it may become epidemic, while virus A may give rise to sporadic cases. There is usually an admixture in any epidemic, although one virus commonly predominates.

Secondary infection undoubtedly plays a very important part in the complicated symptomatology of the disease. It is unfortunate that in bacteriological nomenclatures the term "influenza" is still linked with Pfeiffer's bacillus. For though *Hæmophilus influenzae* is one of the organisms most frequently responsible for secondary infection, it occurs as the causal microbe in cases of disease quite other than clinical influenza—septic endocarditis, sinusitis and meningitis. A special feature seen in regard to it is the fact that, when present in acute cases of influenza, it usually occurs in enormous numbers in the infected tissues and their secretions. Next to *H. influenzae*, the micro-organisms most commonly found in association with the disease are streptococci of the hæmolytic kind, pneumococci, *N. catarrhalis* and *Staphylococcus pyogenes*. It seems certain that many of the most serious and fatal cases owe their lethal character to streptococcal or staphylococcal pneumonia.

Symptoms—So far as can be judged the incubation period is with considerable constancy, something from 24 to 48 hours. A marked feature of the disease is the abruptness of the onset. So abrupt is it at times that the victim is stricken down, as it were, in the street, and, from being quite well he is, within a few hours, prostrated and already suffering the maximum discomforts of the disease. The temperature rises rapidly, there is often a rigor. The chief symptoms are racking headache, intolerable aching pains in the loins and limbs, dryness and irritable redness of the mouth and fauces, and a distressing dry cough. An erythematous rash is not uncommon.

Although the symptoms are protean, it is customary to describe certain types of case that are frequently met with, dependent largely upon the particular tissues and functions which suffer the chief results of the infection. It is to be noted that different outbreaks of the disease are prone to be characterised by different clinical types, as also by differing degrees of severity.

1 *The febrile type*—In this variety of the disease the chief features are pyrexia, with associated malaise, headache, pains in the back and limbs, and a moderate degree of catarrh of the upper air-passages. In many cases this type differs only from the 'common cold' in its more abrupt onset, its higher degree of pyrexia, its disproportionately severe prostration and its relatively "dry" form of catarrh. The eyeballs are often painful, with some conjunctivitis, and the fauces are often red and lightly œdematous and the tongue "dove coloured." Cough is often present, with or without associated pulmonary signs. The pyrexia lasts for a variable time, usually 3 to 6 days, the temperature chart may show two peaks in the 24 hours. It is unusual to see the fever prolonged past the fifth day without some focal complication, generally pulmonary. Defervescence is quite frequently by crisis, but this is by no means the rule.

2 *The respiratory type*—This is the form of the disease which is most prevalent in pandemics, and when severe, it is the form to which the mortality is chiefly due. Somewhere about the fourth day of the disease it becomes obvious that the catarrhal process is growing troublesome, with more definite involvement of the larynx, trachea and bronchial tract. A dry catarrh of the larynx and trachea, with pain and distressing cough, may constitute the main feature of the disease. In many cases the temperature falls about the third or fourth day, to rise again concurrently with a definite exacerbation and extension of the catarrh. The respiratory involvement does not tend to remain localised as a bronchitis, but involves the lung tissue, leading to a bronchiolitis and, in many cases, an alveolitis also. Then ensue the signs of acute pulmonary congestion which are so characteristic of the disease, and cause so much anxiety for

Food than he desires during a short lived illness, but he should be encouraged to drink liberally. The patient is sponged all over with warm water twice daily.

2 *Drugs*—There is no drug which acts as a specific. Aspirin and Dover's powder in gr 10 doses may be given together as early as possible and may be repeated once or twice every 6 or 8 hours. This may be followed by a simple diaphoretic mixture. The sulphonamides and penicillin are only of service when secondary infections are present, and especially when these are of a pulmonary nature.

3 *Treatment of symptoms*—If the headache is severe, phenacetin gr 10 with caffeine gr 2 may be given 4 hourly for four doses. If the stomach gives trouble, and the tongue is foul, sod bicarb and sod sulphocarb, of each gr 10, with glycolic acid carbol min 10, may be given 6 hourly with the feeds, well diluted.

Distressing and persistent cough is often the most difficult problem. Local applications to the chest, including dry cupping, are often of service. If the origin of the cough is irritability of the upper air passages inhalations of tinct benzoin co 4 parts, with menthol or eucalyptus 1 part, are useful. Failing this, a spray containing chlorbutol (Chlorctone) and menthol, 2 per cent of each in liquid paraffin, may be used to the nose and throat. In the "essential cough" of the disease, syr cocainæ co, syr codeinæ and tinct terp heroin co are of some value. In intractable cases relief may follow syr chloral min 30, ammon brom gr 10, with ext glycyrrhiz liq min 20, etc, in 4 hourly doses for 4 doses.

Insomnia calls for a general review of the whole programme—ventilation, control of pyrexia, posture, food, stimulants, etc. Failing attention to these things, a sedative draught of ammon brom gr 20 and tinct valerian min 20 may be tried, if not successful, min 120 doses of paraldehyde, with tinct quillaire and tinct aurantii to cover its unpleasant taste. Failing this, again, chloral and bromide may be given, since drugs of the barbitone group are better avoided.

4 *Treatment of more severe cases and of complications*—(a) *Intensely toxic cases with hyperpyrexia*—Attention to good ventilation should be redoubled. The thermometer and not the patient's sensations must be the guide to the amount of bed clothes. 'Cradling' is often very useful, as also is tepid or spirit sponging. In cases in which the temperature is even then resistant, the cold pack should be used and repeated if necessary. Febrifuge drugs are to be avoided in such cases.

(b) *Pulmonary cases*—In most instances a secondary infection is responsible for pulmonary symptoms. A bacteriological examination of the sputa is desirable, with investigation of the sensitivity of any pathogenic organisms to the antibiotics and the sulphonamides. Penicillin or chlortetracycline should be administered while the results of these tests are awaited. Oxygen delivered through a nasal catheter or B L B mask is useful in all severe cases with cyanosis.

(c) *Heart failure*, to be estimated more by the general state of the patient (facies cyanosis, dyspnoea, delirium, posture) than by pulse-frequency or physical signs, is met by alcohol, strychnine injections, nikethamide (Coramine) subcutaneously, and as a measure supplementary to these, strophanthin gr $\frac{1}{100}$ in 20 min of sterile saline solution, injected slowly into a vein of the arm and repeated, if indications are still present, in 8 or 12 hours.

FOOT-AND-MOUTH DISEASE

Synonyms—Aphtha Epizootica, Epidemic Stomatitis

Definition—A contagious disease, due to a virus, communicated from animals to man, characterised by mild pyrexia, swelling and vesiculation of the tongue and buccal mucosa, accompanied, sometimes, by a vesicular eruption on the hands and fingers.

Ætiology—Man is relatively insusceptible to infection which, however, is of

almost world-wide distribution amongst cattle, pigs and sheep. Up to 1872 there were but few reported cases of supposed foot-and-mouth disease in man. In that year a similar form appeared in cattle, and human cases were more frequently seen. In 1897 analysed the reports of more than 1,500 cases which occur in small groups.

It is recognised by immunological tests: anti-serum (A) and C (Waldman) has no protective influence against two types. In cattle the virus enters through the skin, and septicæmia ensues during which all the secretions are infective, with subsequent localisation in the skin. It is active on hair or in soil for a month. It is communicated to man: (1) By the consumption of milk from the diseased. (2) By direct inoculation: (a) by milking cows suffering from the disease, or (b) by milking cows suffering from the disease whose milk is affected are for the most part either children,

incubation period of foot-and-mouth disease in cattle, namely, 2 to 5 days. Whatever the route of infection, there is at first a slight headache, a mild grade pyrexia and dryness of the mouth for a few days, and is then succeeded by a period of the characteristic lesions—vesicles upon the skin, and a whitish-white turbid fluid. In 48 hours or so the disease is characterised by superficial ulcers having a smooth purplish swelling of the tongue and mouth, which, with the difficulty of swallowing. At the same time a crop of small vesicles appear on the hands; they increase rapidly in size, and fall off early in the second week. In adults recovery is from 7 to 10 days. Occasionally the disease may cause a severe keratoconjunctivitis. In the case of boiled milk, the condition is prone to be more severe, gastro-enteritis and diarrhoea. The treatment is dietetic and symptomatic. A weak solution of potassium permanganate is the best local application; strong antiseptics, such as iodine, must not be employed.

PSITTACOSIS

This disease derived from birds, including parrots, fulmar petrels, resembling typhoid fever in its early stages, but presenting signs of an atypical pneumonia.

In many cases of this disease were derived from parrots, the Indian parrot being usually the source. It is now known to be a communicable disease and may transmit the infection to man; a suitable name for the disease would be ornithosis.

Infection is usually conveyed direct from a sick parrot to a human being who has been in close contact with the bird, but a parrot dead of the disease is also infectious. It is probable that a healthy parrot can act as a carrier. Infection from one human being to another, although it seems to occur occasionally, is very rare. Bedson proved that the causal organism was a filtrable virus and complement-fixation and neutralisation tests have been devised which are of assistance in establishing the diagnosis.

Pathology.—The post-mortem appearances are those of a severe septicæmia, with characteristic changes in the lungs. The latter do not present the picture of classical lobar pneumonia or broncho-pneumonia, but of a "peculiar hæmorrhagic

fear of untoward developments. The respiratory manifestations of influenza infection extend from laryngitis and tracheitis through bronchitis to lobular and lobar pneumonia and pleurisy, both "dry" and with serous or purulent effusion. But the dominant feature, rarely absent in any really severe case, is a condition of capillary bronchitis with intense pulmonary congestion. This may be unilateral or bilateral, is more often basal than apical, but is not seldom universal. The physical signs are copious fine rales (crepitation), with impaired vesicular sound, and, less often, impaired percussion tone. This condition may well be termed the essential lesion of the disease, for even when actual consolidation of the lung is present, this is quite often an incident by comparison, and if the patient dies, he dies with the consolidation rather than of it.

Cough is usually a very troublesome symptom in this type of the disease, and is often quite independent of the need to expectorate. The sputa vary considerably. They may be quite absent, even in cases where there is widespread lung congestion. When present they are generally of a kind that corresponds with the nature of the chief lesion, whether tracheitis, bronchitis or pneumonia. Two special kinds of sputa are very typical of influenza, and they are seen frequently during epidemics. (a) Bright, pink, frothy mucus, sometimes produced in large amount, it may be as much as a pint in 24 hours. This rose red mucus results from acute inflammatory oedema of the lung. It may be expelled involuntarily during cough and sometimes it spurts from the nostrils. (b) Tenacious mucus, less viscid than in lobar pneumonia, and more copious, differing also in colour which is of several hues—red, brown, saffron and various shades of green, all of these being occasionally present at the same time. Seen in a white earthenware vessel these sputa are very striking and in a high degree diagnostic.

3 *The malignant type*—This severe and very fatal form is almost confined to pandemic or to epidemic periods. The patient is gravely ill from the onset, or soon after, with intensely toxic symptoms, cyanosis of a peculiar character ("heliotropic cyanosis") and rapid development of heart failure before focal manifestations have time to show themselves—unless it be the presence of copious fine rales of the kind referred to in (2). The duration of this type of case varies from 48 hours up to a week, and no measures of treatment however prompt, serve to avert the almost certain issue. It is asserted by reliable observers that death may occur even within the first 24 hours from the onset.

There is no evidence that the influenza viruses give rise to an epidemic illness in which abdominal symptoms dominate the picture. "Gastric influenza" is a term which should not be retained. Epidemic nausea and vomiting has been noted in small outbreaks and a "virus diarrhoea" is thought to occur. The causal agents of these diseases have not been identified, but there is no reason to inculcate the influenza viruses.

Complications and Sequelæ—These are both numerous and important. In deed, if we except the malignant cases and the very severe respiratory cases occurring during pan- and epidemic periods, it may be said that the importance of the disease lies more in its complications, and perhaps still more in its sequelæ, than in the stage of infection proper. For convenience these disabilities may be grouped as follows.

1 *Respiratory*—The main extensions of the catarrhal process have been already referred to, as also has the occurrence of pleurisy. Sinusitis may be mentioned here as both common and troublesome. Otitis media also occurs. Asthma sometimes appears for the first time in a patient's life after influenza, and the age of the sufferer may be much more advanced than is usual with asthma generally. Pulmonary tuberculosis not seldom shows itself also for the first time in the same association. The associated pneumonia may be followed by bronchiectasis.

2 *Circulatory*—Perhaps the most serious complication and sequel is referable to the heart. Some degree of cardiac enlargement is common during a severe attack.

of the respiratory type, and this condition is apt to prolong convalescence in a very tedious fashion. In some cases a bradycardia due to heart block has been observed. The prognosis in this condition is good.

Vasomotor troubles are not uncommon and often complicate the heart condition. Phlebitis may occur.

Diagnosis—During paroxysms and epidemics the diagnosis is, as a rule, not difficult, especially when the case is very severe. If the highly characteristic condition of bronchiolitis with copious fine râles referred to on p. 179 be present in a febrile illness with nerve prostration and general toxæmia, the diagnosis is fairly certain. A leucopenia is present in influenza until secondary bacterial infection is established.

The diagnosis of milder cases of influenza, if occurring in sporadic fashion, is frequently a frank admission that it is well to give the patient and his friends a label to his disease. There are so many causes of an acute febrile illness with malaise and slight catarrh that exact clinical diagnosis may not be possible.

Precise diagnosis requires laboratory evidence that the infection is due to one of the influenza viruses. The influenza viruses agglutinate fowl erythrocytes, but this agglutination is inhibited if serum containing antibodies is first added to the virus suspension. These observations have provided a relatively simple method of demonstrating the presence of circulating antibody and the "agglutination inhibition" test has proved a valuable weapon to the epidemiologist. It remains impracticable and unnecessary to seek this laboratory confirmation in routine clinical practice.

A word of warning is perhaps necessary in respect of diseases known to be prevalent coincidentally with outbreaks of influenza. Thus, true pneumococcus pneumonia, whether lobular or lobar, is not infrequently called influenzal when this latter disease is epidemic. Of greater importance is the fact that waves of incidence of influenza and poliomyelitis and encephalitis sometimes concur. If the practitioner's attention is bent only upon the former disease he is apt to put down to it certain serious nerve lesions that really belong to the latter.

Treatment—**PROPHYLACTIC**—As we do not know the factors leading to the production of influenza epidemics we do not know how to prevent them. When they arrive we can to some extent control them by efficient quarantine, by early diagnosis and notification, and by a proper system of hospitalisation adequate to the peculiar features presented by the disease. In regard to individual prophylaxis it was formerly held that to keep generally "fit" was a good protection against infection. But recent experience does not confirm this view. Influenza attacked the strong as well as the weak, indeed the robust young adult fell a victim by preference, though this may have been partly because he was more open to infection by virtue of the conditions of his life. The age mortality as well as the age morbidity during the 1918-1919 pandemic seemed to make it clear that some method of specific immunisation is essential before we can hope to protect against infection. The protection given by vaccines prepared from the viruses is curiously variable, apparently because of the changes in antigenic characters of the prevalent strains. For instance, a mixed virus A and B vaccine which gave good protection against influenza in 1946 was almost ineffective in 1947. Protection is established, experiments with induced influenza have shown within 8 days, but endures for only 4½ months for virus A and about 1 year for virus B. These vaccines have not yet emerged from the experimental stage.

CURATIVE—1 *General measures*—With the onset of symptoms the patient is put to bed and is kept there until the temperature has reached normal and has remained there for 48 hours. Isolation is desirable. He is only allowed up if examination of the heart and lungs, and a review of his general condition, reveal nothing abnormal.

A light easily digestible diet should be given in quantities determined by the patient's appetite. There is no need to press a well nourished patient to take more

vesicular pneumonia, complicated by pulmonary thrombosis and free from bacteria" (Turnbull). In addition, areas of mucopurulent bronchitis and broncho-pneumonia may occur from secondary infection. The gastro-intestinal tract is usually free from severe inflammation.

Symptoms.—The disease usually sets in rather suddenly after an incubation period of 7 to 14, and sometimes as long as 30, days. The rise of temperature is commonly abrupt, and headache is pronounced. Epistaxis sometimes occurs. The patient is generally dull and apathetic, and passes into a condition suggesting a typhoid infection. The abdomen may be slightly distended, and there may be a little sickness and diarrhoea at the outset. The spleen is not palpable, but in some cases a few rose-spots have been observed which are of a smaller size than the spots in typhoid fever. Pulmonary symptoms may be present from the outset, or appear after the disease has lasted some days. Cough is often frequent and troublesome, but, as a rule, there is little expectoration. Respiration may be rapid, but the pulse-rate remains low. The signs in the lung range from those of a bronchial catarrh up to massive, sometimes very dense, consolidation. Pleuritic signs are very rare. The disease usually lasts from 2 to 3 weeks, and the temperature may fall abruptly. Temporary rises of temperature during convalescence are often observed, and there may even be a complete relapse.

Diagnosis.—Clinically the disease can be suspected on circumstantial evidence. If one has a patient who presents a general resemblance to a case of typhoid or paratyphoid fever, but whose blood does not give the agglutination reactions, who presents also pulmonary symptoms and signs of an atypical sort, and who has also been brought into close contact with a sick parrot or love-bird, then the diagnosis is justified. A deceptive feature in the diagnosis from typhoid, however, is that sometimes the agglutination reaction to *Salm. typhi* is positive. It may be impossible at the outset to distinguish psittacosis from influenza, but the supervention of pulmonary complications *within the first few days* is in favour of the latter. Bacteriologically the existence of the disease is proved by the presence of a positive complement fixation reaction in the patient's serum.

Prognosis.—The mortality varies considerably in different epidemics, but may perhaps be put at about 1 in 6. Young people usually recover. Severe involvement of the lungs and failure to maintain a relatively slow pulse are unfavourable factors.

Treatment.—Penicillin has proved of value in some cases, but chlortetracycline is the drug of choice and reports of its action are most encouraging. Patients should be nursed with the usual precautions adopted in a typhoid case, but need not be further isolated. Special signs and symptoms must be treated as they arise.

PROPHYLAXIS consists in forbidding the importation of infected birds; cages should be kept clean, and the birds should not be fondled. A bird which falls sick should be immediately isolated or destroyed.

R. BODLEY SCOTT.

YELLOW FEVER

Synonyms.—Febris Flava; Typhus Icteroides; Yellow Jack; Black Vomit; Kendall's Fever; Fievre Jaune; Fiebre Amarilla.

Definition.—An acute infectious disease of sudden onset, endemic in parts of tropical America and West Africa, characterised typically by pyrexia, vomiting, a slow pulse relative to the temperature, early albuminuria and a tendency to hæmorrhages and jaundice. It is caused by a filtrable virus and is transmitted to man by the common domestic mosquito, *Aedes aegypti* (*Stegomyia fasciata*).

Ætiology.—The endemic haunts of yellow fever have been curtailed in recent years by the destruction of its intermediary host. A circle with its centre in the

Isthmus of Panama, and embracing the northern parts of South America, the West Indian Islands and the southern parts of North America includes most of the area of its late prevalence in the Western Hemisphere. Unsuspected reservoirs of infection have been found in the Amazon basin and in parts of Colombia, Venezuela and Brazil. The endemic area in Africa is regarded as including West, Central and East Africa extending north to the Anglo-Egyptian Sudan and Eritrea and south to the Uganda Protectorate and Belgian Congo. Stokes, Noguchi and Young died when investigating yellow fever, the infection being probably acquired by direct contact with infective blood rather than by the mosquito vector, *Aedes aegypti*. Carroll in 1900 showed that this mosquito would transmit the disease after a period of 12 days, provided it was fed on the blood of a yellow-fever patient during the first 3 days of fever. Reed and Carroll also found that the injection of 0.1 ml. of blood from a yellow-fever patient collected during the first 3 or 4 days of fever produced the disease, and that the serum after filtration remained infective. *Aedes aegypti* bites in the daytime, and is most aggressive in the early morning. Its domestic habits make it an efficient vector, as the larval stages develop mainly in artificial containers in or near human habitations. Males and females are equally susceptible, and infection in childhood is common. This type of urban and rural yellow fever differs from jungle yellow fever, which is found in or near tropical forests in Brazil, where *Aedes aegypti* is absent. Adult males who work in the jungle are mainly infected. Wild jungle mosquitoes have been found to harbour the virus, but the common vector is not yet known. Monkeys and possibly the hedgehog or other susceptible animals may play an important rôle as reservoir hosts. In 1927 the West African Yellow Fever Commission found that the Rhesus monkey (*Macaca mulatta*) was susceptible, only 1 out of 30 monkeys surviving. One attack confers lifelong immunity, and 0.1 ml. of convalescent human serum protects monkeys. The virus, if dried, will keep for months, it penetrates the intact skin of both man and monkeys, but is no longer demonstrable in the blood and viscera after the fourth day.

The diameter of the virus as determined by filtration through collodion membranes lies between 17 to 28 millimicrons. It possesses two qualities, viscerotropism and neurotropism, when both are present it is known as 'pantropic' virus. In 1930 Theiler found that if pantropic virus was inoculated intracerebrally into susceptible mice they developed encephalitis, unless immune serum was simultaneously injected. After repeated passage through the brain of mice the virus lost its viscerotropism or capacity to attack the abdominal and thoracic organs, and was converted into a neurotropic virus with fixed characters. Injection of this virus or of pantropic virus attenuated by tissue culture immunises against yellow fever and is the basis of prophylactic immunisation.

The fact that immune bodies are demonstrable in the blood of yellow fever cases shortly after infection, and persist permanently in recovered cases has been utilised to determine the endemic incidence of the disease. Mice are employed for the purpose. The protection test, as developed by Sawyer and Lloyd, consists of an intracerebral inoculation of starch solution followed by the intraperitoneal injection of virus and the serum to be tested. In the absence of immune bodies in the serum the virus produces encephalitis and death within a fortnight, if immune bodies are present the animal remains unaffected. This test has been of great value in affording an index to past epidemics, and in accurately determining the past and present geographical distribution of the disease. Examination of liver specimens obtained by means of the viscerotomy from persons dying of illness of not over 10 days' duration has also led to the detection of unsuspected reservoirs of infection.

Pathology.—Death generally occurs between the fifth and ninth day of the disease. Rigor mortis comes on early. The skin may show ecchymoses and is an intense yellow colour, which becomes accentuated after death. The liver is of approximately normal size, reddish yellow, brownish yellow or 'chamois leather' colour,

and may show hæmorrhages. Microscopically a midzonal fatty degeneration is characteristic on the fourth or fifth day, but later all zones undergo necrosis, and the nuclei may contain acidophile inclusion bodies. The gall-bladder contains tenacious, dark bile. The kidneys are congested, and show cloudy swelling and fatty degeneration. Petechial hæmorrhages, casts and degeneration of the convoluted tubules are seen on section. The adrenals may show cortical fatty degeneration. The left ventricle is often dilated, and its muscle pale and flabby. Bradycardia is due to damage to the auriculo-ventricular bundle, and fatty degeneration of muscle cell-elements are common. Erosions and petechial hæmorrhage in the stomach and proximal duodenum occur, hence the coffee-ground vomit and the tarry blood in the entero colon. The spleen is almost normal in size and appearance. The pleura and meninges may show hæmorrhages, the brain is congested, and the lungs congested and apt to show hæmorrhages.

Clinical pathology—The outstanding pathological features are cloudy swelling and necrosis of the parenchymatous cells, especially of the liver and kidneys, and degeneration of the capillary endothelium, resulting in hæmorrhages. Jaundice and albuminuria with casts are thus produced. Hypoglycæmia related to liver inefficiency may occur from the fourth day onwards, while the van den Bergh may show a biphasic direct positive reaction and a positive indirect reaction of from 2 to 20 units. In the later stages the blood urea may be increased, and in monkeys Findlay found an increase in guanidine bodies. Though the leucocytes may vary from 3000 to 15,000 per c mm, leucopenia is the rule, the lowest counts occurring about the fifth to sixth day, the neutrophiles are decreased, the lymphocytes increased and the eosinophiles tend to disappear. The clotting time is markedly increased. The cerebrospinal fluid is under increased pressure and may contain increased quantities of albumin and chlorides.

Symptoms—The incubation period is from 3 to 5 days, but may be 10. Clinically, the disease is divided into (1) Larval and mild forms, (2) Severe, (3) Malignant. In well established severe cases the clinical features vary according as the liver, kidneys or heart bear the brunt of the attack, acute hepatitis and cholæmia, uræmia and anuria, and cardiac insufficiency being respectively manifest. Most cases show evidence of both renal and hepatic involvement.

1 *The larval and mild types*—During epidemics, as well as where the disease is endemic, aberrant and irregular types are not infrequent, transient fever of 1 to 4 days' duration, perhaps associated with albuminuria, occurs with rapid return to health. Where the pyrexia persists over 48 hours, headache, vomiting, eye pain and mild jaundice may ensue. Diagnosis in the larval forms is dependent on showing that convalescent serum is protective.

2 *Severe or ordinary types*—The typical case presents three stages: (a) the sthenic, (b) the stage of remission on the third or fourth day, (c) the asthenic stage. In the *sthenic stage* the onset, which often occurs at night, is sudden with chilly sensations or a rigor, the temperature rapidly rising to 102° F or 104° F. There is severe pain in the back and limbs, frontal headache with flushed face, injected conjunctivæ (ferret eye) and photophobia. Prostration is severe, often disproportionately so to the temperature (Carter). The tongue is pointed and red, anorexia, nausea and vomiting, which may be bilious, appear. Epigastric discomfort and tenderness are characteristic, and insomnia is frequent. Albuminuria generally occurs on the second day and steadily increases. The pulse is at first rapid (90 to 110 per minute) and of high tension with raised blood pressure, but later slows until by the third day it may be 60 to 70 per minute despite the fact that the temperature remains elevated. This is known as Faget's sign, the pulse actually falling away from the temperature. It also remains slow when the temperature rises again in the relapse. Constipation is the rule.

Stage of remission—About the third or fourth day the temperature may fall to

100° F or lower with amelioration of symptoms. Recovery may result or fever be re established. Frequently this stage is absent altogether.

The asthenic stage—The temperature rises again if it has remitted, turgidity of the face decreases, and jaundice now appears; it is first seen in the conjunctivæ and is not obvious in the skin until the fourth day of fever as a rule, sometimes, however, it is demonstrable on the third day. The gums are swollen and bleed on pressure, while the tongue is coated and later becomes dry and brown. The liver is tender and only slightly, if at all, enlarged, while the spleen is not palpable. Hiccough may be very distressing, and black or "coffee ground" vomit, tarry stools and skin petechiæ may occur. Bradycardia is marked (40 to 60 per minute) and the blood pressure low. The urine is acid and decreased in quantity; it contains urobilin and much albumin, granular casts and possibly bile salts, bile pigments, bile-stained epithelial cells and red blood corpuscles. Anuria is frequent in fatal cases. After the intermission, the fever does not last as a rule more than 3 days.

Malignant forms—In this type the temperature may reach 106° F and profuse hæmorrhages, melæna, black vomit, epistaxis, hæmaturia, purpura, jaundice and anuria may develop by the third day. Symptoms referable to the nervous system such as hiccough, tremor, subsultus tendinum and delirium are also encountered, death from overwhelming toxæmia rapidly ensuing.

Complications—Complications are uncommon, but boils, abscesses and troublesome jaundice, appearing for the first time in convalescence, may occur.

Diagnosis.—Difficulties in diagnosis are mainly encountered in atypical cases, especially early in an epidemic. In the average case fever associated with undue prostration and early and increasing albuminuria should at once arouse suspicion, while later, the tender liver, absence of splenic enlargement, Faget's sign, hæmorrhages and jaundice appearing about the fourth day will be confirmatory. In black-water fever, jaundice appears in the first 24 hours, in bilious remittent fever on or about the second day, while in Weil's disease it is generally found on the fourth or fifth day. Dengue, malignant tertian malaria and relapsing fever also occasionally give rise to difficulty in diagnosis. Malaria, bilious remittent fever and relapsing fever are generally associated with an enlarged spleen, while blood smears should reveal malaria parasites or spirochætes. Special laboratory investigations may be necessary to differentiate Weil's disease. In the larval forms of yellow fever intracerebral inoculation of susceptible mice with 0.03 ml of blood collected during the first 3 days of fever may reveal the virus. More frequently it will be necessary to take two specimens of blood at a fortnight's interval and establish a rise in the titre of protective antibody by the mouse protection test in order to establish the diagnosis.

Course—If the patient survives, the acute disease rarely lasts longer than 10 days, and convalescence generally progresses slowly but surely once a normal temperature is established. Relapses are rare and generally fatal.

Prognosis—The prognosis differs in various epidemics, the mortality rate varying from 10 to 70 per cent, the average being 20 to 30 per cent. Anuria, deep jaundice, black vomit, hæmorrhages and severe nervous disturbances are of grave significance.

Treatment—**PROPHYLACTIC**.—The segregation of infected individuals in mosquito-protected wards, and the destruction of the adult and larval stages of mosquitoes (*Aedes*) have done much to stamp out the disease. Rubber gloves should be worn in collecting blood from all pyrexial cases in endemic areas. Convalescent serum affords temporary protection. All persons visiting or living in a yellow-fever area should be vaccinated with virus modified by tissue culture. A single subcutaneous injection of 0.5 to 1.0 ml produces protective antibodies and confers an immunity which probably lasts 4 years. No local reaction follows inoculation, but headache and general aching may develop about the fifth day. Jaundice has frequently followed some 3 months after inoculation, but this is not due to the yellow-fever virus, but to the use of human serum containing the icterogenic factor.

CURATIVE.—Careful nursing of the patient in the recumbent position is essential, and as much fluid as can be taken is given during the acute illness, but food is contra-indicated. The juice of citrus fruits and dextrose and lactose are given in water; citrates should be added to the drinks to combat acidosis. Only when the temperature has been normal after the second paroxysm can a gradual increase in food be permitted—rice water, chicken soup, Benger's, custard, etc.—and even in convalescence it is only gradually increased. In severe cases with vomiting, 2 pints of 5 per cent. dextrose, given intravenously every 24 hours, may be helpful; also tap water may be administered per rectum. Calcium lactate, gr. 60 daily, is advocated to neutralise the effects of guanidine intoxication. Unfortunately, though protective to monkeys when given in the incubation period, convalescent serum does not affect the course of the disease once symptoms have appeared. Symptomatic treatment includes the use of an ice bag locally for headache, a mustard plaster to the epigastrium for hic-cough, hot fomentations and catheterisation for retention and sedatives for insomnia. Champagne may help the vomiting. On admission a mild purgative is administered and constipation is subsequently treated by a daily enema. A cold sponge is indicated when the temperature exceeds 103° F.

PHLEBOTOMUS FEVER

Synonyms.—Papataci Fever; Three-day Fever; Sand-fly Fever; Pym's Fever; Dog's Disease.

Definition.—An acute specific fever lasting about 3 days due to a filterable virus and spread by *Phlebotomus papatasi*.

Ætiology.—The disease occurs in parts of Africa, Asia, Northern Argentina and is common in the Mediterranean basin, in India, Mesopotamia, Persia, etc., where it affects especially white races, though natives also suffer. Many thousands of troops were affected in the Middle East during 1940-1944. The virus is present in the peripheral blood for the first 24 to 48 hours, and female sand-flies sucking up such blood become infective 6 or 7 days later, and remain so for life (Doerr). The virus may also be transmitted by the female *Phlebotomus* to the egg and larva (Moshkovsky). Blood taken on the first and second days may produce the disease on experimental inoculation, and volunteers bitten by infective sand-flies develop fever in 2 to 7 days. One attack generally confers relative immunity, but second attacks are not uncommon.

The disease occurs in the summer and early autumn in the subtropics, as *Phlebotomus papatasi* passes the winter months in its larval stage. It breeds in cracks and crevices affording moisture, darkness and organic matter, and is found in stone and rubble walls, dug-outs, trenches and surface soil. The adults shelter in similar situations. The females bite just after sunset and at dawn. Numerous bites occur over the wrists and ankles, where they produce itchy papules, which may vesiculate and give rise to localised swelling. The itching is severe, and may persist for 48 hours or longer or recur after an interval of several days in a sensitised individual who is rebitten.

Pathology.—This has been inadequately studied, as the disease is not fatal.

Symptoms.—The incubation period is 2 to 7 days. Prodromata, such as malaise, vague pains, headache and weariness, may usher in the disease. Generally the attacks commence suddenly with chilliness, shivering, lumbar pain and malaise. Rigors occasionally occur. The fever is short and sharp, reaching 101° F. to 104° F. by the evening of the first day. Severe frontal headache, increased by coughing, retro-ocular pain, accentuated by movement of the eyes or pressure on the globes, and toxic pains and stiffness in the muscles of the back, neck and legs are characteristic. The face is flushed and perhaps swollen, the conjunctivæ are injected (Dog's Disease), the skin is hot and dry, the tongue has a central fur, the throat is congested, and

the fauces and palate are sometimes studded with small vesicles. Bradycardia is a feature of the disease. Sleeplessness and irritability are common. The cerebro-spinal fluid may sometimes show increased pressure, some lymphocytes (10 to 30 per c.mm.), an increase in albumin, and a decrease in chloride. The blood picture shows a leucopenia with a relative lymphocytosis. Epigastric discomfort, nausea, vomiting and constipation may occur; occasionally diarrhoea is encountered.

After about 36 hours, the temperature begins to fall and reaches normal in 3 or 4 days. There may be concomitant sweating, vomiting, diarrhoea and epistaxis. Occasionally the fever only lasts for 2 days, and rarely it exceeds 4 days.

Diagnosis.—In the early stages it may be impossible to make a diagnosis with certainty. Influenza, dengue, paratyphoid, malaria, relapsing fever, typhus, infective hepatitis and other fevers may need differentiation. In influenza the upper respiratory tract involvement, and in dengue the secondary rash and the more prolonged or saddle-back type of temperature, may assist diagnosis.

Prognosis.—Recrudescences are exceptional. The disease is never fatal. Convalescence is generally rapid, but extreme depression, malaise, asthenia and digestive disturbances may persist for 1 or 2 weeks.

Treatment.—**PROPHYLACTIC.**—Combined outdoor and indoor spraying with D.D.T. has revolutionised the control of sand-flies, while the use of the repellent dimethyl-phthalate to the ankles, wrists and exposed parts at sunset has proved most effective. At night sand-fly nets or mosquito nets impregnated with D.D.T. should be used.

CURATIVE.—Cases are treated by light diet, rest in bed during the febrile period, cold sponging when the temperature exceeds 103° F., and a mixture of aspirin, phenacetin and caffeine citrate.

DENGUE

Synonyms.—Dandy Fever; Break-Bone Fever.

Definition.—A specific fever, lasting 5 to 7 days, caused by a filtrable virus which is transmitted by *Aedes aegypti* or certain other species of this genus. A saddle-back temperature chart, severe rheumatic-like pains in the limbs, backache, bradycardia, leucopenia and a measles-like eruption appearing about the third-fourth day are characteristic. Many atypical clinical forms occur.

Ætiology.—The disease occurs universally throughout the tropics and sub-tropics, where it is often endemic; from time to time explosive epidemics or pandemics arise. All ages and both sexes are liable to infection. The virus is filterable, and exists in the blood for some 18 hours before onset and for the first 3 days of fever. It is communicable to man by direct blood inoculation during this period, or by the bites of certain species of *Aedes* mosquitoes. The mosquito takes 11 to 14 days to become infective, and remains so for life. The common vector is the domestic mosquito, *Aedes aegypti*, and owing to its habits the disease is especially common in towns on the sea coast. *Aedes albopictus* also transmits dengue in the Philippines, while *Aedes scutellaris* has recently been proved to transmit dengue to troops in New Guinea in areas in which *Aedes aegypti* is absent. The same virus transmitted experimentally to volunteers by the same batch of mosquitoes can give rise to a very variable clinical picture. Some volunteers fail to develop fever, though their blood contains the virus; others may have a two-day fever; others a saddle-back type of temperature chart; and others continued fever of 5 to 7 days' duration. Demonstrable immunity follows experimental infection. Immunity also develops following natural infection, and when individuals suffer second or third attacks of dengue these tend to be of lessened intensity. The fact that large epidemics are separated by intervals of many years appears to depend on acquired immunity in the local population. Newcomers

are always most prone to the disease. Dengue has now been transmitted to mice and an attenuated strain obtained which seems promising for immunisation.

Pathology—Nothing definite is known of this, as the disease is only fatal in the presence of complications or intercurrent disease.

Symptoms—In epidemics, the severity and clinical picture vary considerably at different times and in different areas, and though typical cases are always recognisable many atypical ones are encountered which do not conform to the classical picture.

The incubation period is generally 5 to 10 days. In the typical case, three phases are recognised: (1) the stage of invasion, (2) the stage of remission and (3) the stage of secondary rash and terminal fever. Prodromata include general malaise and pains in the limbs. Generally the onset is absolutely sudden, with a rapidly rising temperature of 102°F to 105°F , associated with headache and aching eyeballs, more marked on movement. The skin, especially of the face, is congested and shows a general flushing—the so called primary rash. Backache is very severe and much pain occurs at the muscular insertion about the joints. Insomnia, initial depression, anorexia, vomiting and constipation are not infrequent. The pulse at first rapid soon begins to slow and after 3 to 4 days the temperature falls by crisis, this may be accompanied by diarrhoea, sweating and epistaxis. Symptoms now improve, but after 12 hours to 3 days the temperature rises again producing the saddle back chart. Pains and depression recur and a roseolar rash, fading on pressure, appears, it is best seen on the dorsal surface of the hands and feet but also involves the face, neck and trunk. The rash simulates measles but lacks its dusky red appearance. Occasionally it is punctiform and then somewhat resembles the eruption of scarlet fever. A rose red flush of the palms of the hands and soles of the feet is not infrequent. Occasionally dengue rashes become petechial. The desquamation is furfuraceous in type, may be associated with marked itching and may persist for 2 weeks. A leucopenia with lymphocytosis is characteristic. Glandular enlargements may occur, and in some epidemics adenitis is present in at least 50 per cent of cases. Two or 3 days after the secondary fever and rash appear, the temperature falls and convalescence begins.

Other clinical types are frequently encountered. One type presents a one phase fever like sand fly lasting 2 to 3 days, another is characterised by continued fever of 5 to 7 days duration with a terminal crisis, the rash is by no means invariable.

Complications and Sequelæ—General debility, asthenia, anorexia, insomnia and mental depression may persist well into convalescence and persistent rheumatic like muscular pains in the vicinity of the joints may prove very troublesome.

Diagnosis—Influenza, sand fly fever, yellow fever, rheumatic fever, measles, German measles, scarlet fever, secondary syphilis, leptospirosis, malaria, paratyphoid and typhus may be confused with dengue. The respiratory involvement in influenza, the early albuminuria and jaundice in yellow fever, the swollen joints in rheumatic fever, Koplik's spots and early coryza of measles, the rapid pulse, adenitis and leucocytosis in scarlet fever—these will often enable a diagnosis to be made. Specific laboratory tests, the clinical features and the course of the disease will assist in differentiating the other maladies mentioned.

Prognosis—Different epidemics vary in virulence but the death rate is extremely small.

Treatment—**PROPHYLACTIC**—Prevention of breeding and destruction of the larvæ and adult mosquito vectors will prevent the disease. As *Aedes* is a day biting mosquito, it is important to treat all dengue patients under mosquito nets for the first 3 days of their fever and for hospital staffs to use anti mosquito repellent lotions and take other appropriate precautions in daylight hours as well as at night.

CURATIVE—No specific treatment is available. The patient should be kept in bed on a light diet for at least 3 days after the fever has terminated. An aspirin,

phenacetin and caffeine citrate mixture is helpful for toxic pains, and sedatives and cold sponging may be necessary to induce sleep.

During convalescence, tonics, good food and a change of climate may be necessary to restore health in asthenic and depressed dengue patients.

LYMPHOGRANULOMA INGUINALE

Synonyms—Climatic Bubo, Tropical Bubo; Lymphopathia Venereum, Lymphogranuloma venereum, Poradenitis.

Definition.—A venereal disease, due to a filterable virus, characterised by a herpetiform chancre on the genitalia or peri-anal region, inflammation of the corresponding regional lymphatic glands, and fever. In males the inguino cruro iliac glands and in females the perirectal and pelvic glands are chiefly involved. Chronic ulceration and elephantiasis of the pudenda are not uncommon in females, and inflammatory stricture of the rectum may occur in both sexes.

Ætiology.—The disease has a world-wide distribution, but is especially common in China, Japan, Malaya, East and West Africa, and in North and South America. Though more common amongst coloured races, especially negroes, it is being recognised with increasing frequency in Europe. The disease occurs mainly in adults, is essentially venereal in origin and is commonly acquired in the tropics and subtropics following coitus with native women. Sailors often acquire the disease in Eastern ports. The virus particle has a diameter of 0.125 to 0.175 μ , is filtrable and was first successfully transmitted to monkeys by intracerebral inoculation of bubo pus by Hellerström and Wassen. Mice are similarly susceptible. Serologically the virus is closely related to that of psittacosis. In guinea-pigs large buboes may follow the subcutaneous injection of sterile bubo pus. Surgeons have developed axillary buboes from lesions on the fingers when operating on infected patients, and children have acquired infection from simple contact.

Pathology.—The extirpated glands show marked peradenitis, and form conglomerated masses. The cut section often presents a reddish or violet tinge. Foci of purulent softening may occur, and sometimes cavities, containing thick viscid pus of a grey to light green colour, are produced by their coalescence. Microscopical sections of the bubo reveal granulomatous tissue, epithelioid cells, fibroblasts, occasional giant cells and polymorphonuclear leucocytes, epithelioid cells with palisade arrangement are very characteristic. Chromatin staining inclusion bodies, known as Gamma bodies, are found within lymphocytes and plasmocytes in the infected glands.

Symptoms.—In males, the primary lesion is as a rule overlooked. It occurs as a small herpetiform ulcer, generally situated in the coronal sulcus on the penis, and appears a few days to 3 weeks after coitus. Swelling of the median group of inguinal glands draining the ano genital region follows in about 2 or 3 weeks, the limits being 1 to 6 weeks. Bilateral glandular involvement occurs in 35 per cent of the cases. The onset is generally insidious, with slight stiffness or tenderness in the groin, and fever. Often pain is absent, rarely it may be severe. The skin is at first red, but as swelling of the glands with peradenitis and hard brawny infiltration proceeds, it changes to a bluish violet tint. The conglomerated glands are hard to the touch, generally only slightly tender, and show no fluctuation unless suppuration is advanced. *Fistulæ* form in about half the cases. Though the iliac glands are frequently enlarged and palpable, they never present clinical evidence of suppuration. Healing with scarring may occur within 2 months or be delayed 1½ years. The general symptoms include fever, anorexia, weakness and loss of weight. Although the fever is usually remittent in type no characteristic temperature chart is present, and not infrequently the temperature becomes normal in 7 to 10 days, but sometimes it is prolonged and a typhoid-like state supervenes. Recurrent fever is occasionally

associated with extension of the adenitis. Rheumatic and allergic skin manifestations are not uncommon, and include painful red swollen joints, erythema nodosum, erythema multiforme, scarlatiniform and urticarial eruptions.

In females, primary lesions may occur on the genitalia or peri-anal region, and the para-rectal glands are commonly involved; these glands often suppurate and form fistulae which may open into the vagina, the rectum or the skin near the anus. The disease runs a chronic course; fibrous stricture of the urethra, vagina and rectum may develop, or elephantiasis of the vulva (esthiomene) follow lymphatic obstruction. Polypoid swellings may occur about the anus, while the lower portion of the rectum may ulcerate and become converted into a narrow indurated ulcerated tube, with widespread fistulae below the stricture. According to Stannus this is generally situated some 3 to 8 cm. above the anus. Rectal stricture is more common in females—especially in prostitutes—and is associated with the passage of blood, mucus and pus from the bowel, and increasing constipation.

Diagnosis.—Climatic bubo has been called the sixth venereal disease, and the history and clinical features are most important in making a correct diagnosis. Where peradenitis and induration are extreme, actinomycosis may be simulated. Herpes genitalis, filarial adenitis, septic and tuberculous adenitis, venereal bubo the result of chancroid, gonorrhoea and syphilis, as well as other buboes, such as result from plague, rat-bite fever and tularemia, may need differentiation. Histological section of material obtained at biopsy and Frei's intradermal test, using a 1 in 10 dilution of virus-containing pus sterilised at 60° C., may be of assistance; in 0.1 ml. of this antigen is injected intradermally, readings being made at the end of 48 hours. A positive reaction is characterised by the appearance of a reddish, infiltrated papule, measuring from 7.5 to 20 mm. in diameter. It is regarded as a manifestation of cutaneous allergy, and is said to be specific for climatic bubo. Animal inoculation and the mouse protection test may be resorted to in doubtful cases.

Lesions in the ano-genital region must be differentiated from filarial elephantiasis and ulcerative granuloma pudenda. Polypoid swellings should be distinguished from piles, simple polyposis and bilharzia polyps. Rectal stricture which is not due to surgical or other trauma or new growth is almost certainly caused by this virus; in the past it has generally been erroneously attributed to gonorrhoea, chancroid, syphilis or tuberculosis.

Prognosis.—The disease runs a different course in different individuals. In males, unless the rectum be involved, the outlook is good though the disease may last many months. In females, with extensive ano-genital manifestations, such as fibrous strictures and multiple fistulae, permanent invalidism may result.

Treatment.—The patient should be put to bed, have a nutritious high vitamin diet and given a course of sulphadiazine or some similar sulphonamide, as some patients appear to be cured by this treatment. Chlortetracycline, in doses of 500 mg 6-hourly for 10 days, associated with complete rest in bed, is successful in many cases in causing a rapid improvement of the clinical condition. Chloramphenicol is also effective. If the glands are small and have not suppurated they are best left alone. If suppuration has taken place, aseptic aspiration of the pus may be undertaken to prevent rupture and secondary infection.

RABIES (see p. 1420).

EPIDEMIC MYALGIA

Synonyms.—Epidemic or Infectious Pleurodynia, Bornholm Disease; Epidemic Diaphragmatic Spasm, Devil's Grip

Definition.—An acute infectious epidemic disease of short duration characterised by sudden onset of pain in the upper abdomen and lower thorax, pyrexia, sweating and a tendency to relapse.

Ætiology.—The disease occurs usually in the late summer and autumn; it mainly affects children under 15 years of age. The incubation period being 2 to 5 days, the patient remains infective so long as the pain persists. One attack may not confer lasting immunity. Although proof is not absolute, it is probable that infection with one of the Coxsackie group of viruses is responsible.

Pathology.—Nothing is known of the pathology. No abnormality has been detected in those cases in which an exploratory laparotomy has been performed owing to mistaken diagnosis

Clinical Features.—The onset is sudden, with acute spasmodic pain in the region of the xiphisternum and the attachment of the diaphragm, perhaps more on one side than the other. The pain leads to shallow rapid respiration, and is intensified by deep breathing, by yawning, sneezing or cough, a spasm during a period of quiescence may be induced by laughing. In adults, pain may also be complained of in the neck and extremities, and there may be some frontal headache. The temperature rises rapidly, perhaps to 104° F., and subsides within 24 hours. There is a marked tendency to a return of pain and pyrexia during 3 or 4 days, and the second attack may be the more severe. Profuse sweats are common, anorexia the rule, while vomiting and diarrhoea are seldom met with.

There are usually no physical signs, other than in the character of the respiration, if involvement of the pleura, lung or peritoneum, but occasionally coarse pleural friction makes its appearance. There may be some cutaneous hyperæsthesia and tenderness on pressure in the painful area, especially in the epigastrium. In some cases a leucocytosis occurs, and eosinophilia has been reported during convalescence. No abnormality has been detected on radiographic examination.

Complications are infrequent. Conjunctivitis, catarrh of the upper respiratory tract, orchitis and, rarely, meningo-encephalitis have been reported in certain epidemics. There are no sequelæ. Prognosis is good.

Treatment.—The patient should be isolated, and remain in bed until 48 hours after the pyrexia and pain have subsided. Ordinary methods for the relief of pain are indicated.

C. THE MYCOSES

Numerous fungi are pathogenic to man, and the lesions caused thereby are conveniently described as the mycoses.

Some of the diseases, for example the ringworms, are described in other sections. Nine of them will be described here—actinomycosis, sporotrichosis, aspergillosis, mycetoma, torulosis, North American blastomycosis, South American blastomycosis, coccidioidosis and rhinosporidiosis, the lesions of which are of the nature of infective granulomata.

ACTINOMYCOSIS

Synonym.—Ray-fungus Disease

Definition.—A local infection, tending to become general, due to *Actinomyces israeli* or other of several species of the genus *Nocardia*, producing granulomatous lesions chiefly in the jaw, skin, lung and digestive tract.

Ætiology.—*A. bovis* was first described by Bollinger in 1877 as the micro-organism producing large, hard, sarcomatous-like masses occurring about the jaw-bones of cattle, and in the following year Wolff and Israel found a similar organism, now known as *A. israeli*, in human cases. There are two groups of organisms which may cause actinomycosis, *A. israeli*, which is anaerobic, and several species of aerobic *Nocardia*. The second have been isolated from soil, but the first, although frequently present in the healthy mouth, have not been found in soil or in vegetable matter. The two varieties are each responsible for about half the human infections. There is reason to believe that *A. israeli*, normally saprophytic, may become invasive when tissue is injured; the aerobic actinomycetes of soil are conveyed by inhalation or ingestion.

Pathology.—The characteristic of the disease is a suppurative lesion, the pus from which contains visible granules which, examined microscopically, are seen to have a centre of a closely meshed filamentous network, with a border of radially arranged striations, often ending in club-shaped bodies. Formerly these club-shaped bodies were thought to be spores, but they are now regarded as hyaline thickenings of the sheaths of the threads. The clubs are only found in preparations made from pus from active lesions, or in cultures on media in which serum or blood is employed.

It is essential in examining suspected pus to isolate a granule. If granules be not readily detected in the wound or in the pus, Colebrook has pointed out that if pus be vigorously shaken in a tube of water the granules, not being emulsified, will sink to the bottom and may be removed by a pipette. Microscopical examination is very much facilitated by crushing the granules between two slides. The mycelial filaments retain Gram's stain, while the clubs lose it and take the counter-stain. Culture is in any case difficult, depending to a large extent on the amount of secondary infection. To eliminate this as far as possible the granules should be well shaken in a sterile saline solution, and then after crushing between sterile slides should be sown on to glucose agar plates which are incubated anaerobically, or crushed granules may be shaken up into melted glucose agar which is aspirated into long sterile tubes according to the method of Vignal. Numerous subcultures may be necessary to complete the isolation of the organism.

Symptoms.—These depend upon the anatomical distribution of the granulomata

1. **THE JAW AND ADJACENT STRUCTURES.**—When the infection occurs in these parts the patient presents a swelling very like a sarcoma, generally about the angle or ramus of the mandible. The swelling may, however, affect the submandibular tissues and lymph glands rather more than the jaw itself, or even be confined to the glands. The swelling is tender, somewhat painful and not generally so hard as in sarcoma. It may show one or more spots of softer consistency than the rest of the lump. With progress of the disease abscesses form and point externally to give rise to multiple sinuses. In most cases there is no obvious source of infection inside the mouth; the assumption is—in the light of observations quoted above—that the avenue of invasion is a carious tooth, or the gums and peri-odontal membrane.

2. **THE INTESTINES; APPENDICITIS.**—The favourite site of infection is the cæcum and appendix region. The disease manifests itself either as an attack of appendicitis, most often acute, in which case the diagnosis is made only at the time of laparotomy; or as a slowly growing mass in the right iliac fossa, with some pain, tenderness and constitutional disturbance, in which case suspicion may be aroused as to its nature, if it be remembered that this region is a site of election for the ray fungus. Distinction must be made from a swelling due to regional ileitis (see p. 631), to tuberculosis or new growth. There is a tendency for the infection to spread from the ileo-cæcal region—(a) to the adjacent peritoneum; (b) to the abdominal wall; (c) to the liver. For this reason it is rare to find the lesion confined to the appendix by the time operation takes place. For this reason, too, the first evidence of cæcal infection may be the involvement of the parietes in the lower right quadrant of the abdomen, in which

case there is always a probability that the infection has spread from the bowel. The liver is sometimes involved alone, that is, without obvious intestinal infection. The disease is only to be distinguished from abscess by puncture or by free incision.

3 THE PLEURA AND LUNG—Actinomycosis in these tissues is by no means rare (see p 1038), and the disease should constantly be borne in mind by the practitioner when faced with an obscure case in which indefinite physical signs appear at one base, with cough, fever and (not seldom) hæmoptysis. In some cases a fairly frank pleuritic effusion appears, and the bacteriological examination of the exudate reveals the nature of the disease. In other cases the clinical picture resembles a basal tuberculosis. As the disease progresses the differential diagnosis lies between ray fungus, bronchiectasis and new growth. Hæmoptysis which recurs in the absence of any evidence of tuberculosis in an obscure case of pulmonary disease, should raise the suspicion of actinomycosis of the lung. The later stages of the disease still resemble pulmonary tuberculosis, wasting, intermittent fever, purulent expectoration, cough and physical signs of progressive lung infiltration with destruction.

4 THE SKIN—Granulomata sometimes appear in the skin and subcutaneous tissues (a) alone, or (b) complicating the disease in deeper structures.

(a) The neck and scalp are the parts most often affected. The initial lesion is a rounded swelling, resembling a tuberculoma rather than the result of a pyogenic infection, but usually firmer in texture and larger than the lesion seen in tuberculosis of the skin. It has therefore to be distinguished from sarcoma and from gumma. As the lesion progresses it involves the subcutaneous tissue and tends to ulcerate, after the appearance of one or more soft and dusky-red areas on it. When ulceration occurs at these points, pus escapes, and this contains the tell tale granules characteristic of the infection. At this stage the appearance is not unlike that of a chronic carbuncle or a suppurating gumma. Ultimately the skin "breaks down" over a considerable area of the swelling, and a chronic ulcer forms, which discharges freely.

(b) Similar skin lesions appear not seldom in association with primary infections of deeper structures, these superficial deposits having the significance of metastatic pyæmic deposits.

5 THE BRAIN—The brain, like the skin, may be infected by direct spread from an adjacent lesion, or it may suffer by way of a general pyæmic process.

Diagnosis—Hints have been given in the preceding account relative to the differential diagnosis from tuberculoma, sarcoma, pyogenic infection and gumma. The chief reason why actinomycosis goes unrecognised is that the possibility of its existence is overlooked. All materials from a suspected case (pus, pleural exudate, sputa, material from liver puncture, excised lymph glands, etc.) should be carefully examined for mycelium, and the bacteriologist should have his attention drawn to the possibility of its presence. Sputa from a case of recurring hæmoptysis, in which a negative report in respect of tubercle bacilli has been returned on several occasions, have been found to contain threads of actinomyces when the necessary investigation has been specially asked for.

Course and Prognosis—Although these vary much, there is, as may be inferred from remarks already made, a tendency for ray-fungus infection to become pyæmic in character. It is this feature which gives the serious note to prognosis in all cases. In lesions about the jaw and in skin infections, that are primary and not associated with visceral infection, the outlook is not nearly so bad as when the lungs, liver or intestinal tract are involved and when the skin lesions are multiple and secondary. Early diagnosis if possible before secondary infection (usually staphylococcus) has taken place, adds greatly to the chance of recovery. One of the most important points in connection with prognosis is the uncertainty as to the complete extirpation of the fungus after treatment has been apparently successful. Relapses are common, and must be allowed for in any thorough programme of treatment.

Treatment—So soon as the diagnosis is made, penicillin should be given in combination with one of the sulphonamides and the question should be raised whether or not radical surgical measures are practicable. If they are, they should be pursued without delay, any abscess or infected area should be drained, or incised and freely curetted, infected lymph glands should be excised, doubtful teeth should be sacrificed.

Radiotherapy has also been advocated as a supplementary measure.

SPOROTRICHOSIS

In this disease, which is much less common than actinomycosis, lesions (granulomata) appear in the skin, and rarely in the muscles and bones.

Ætiology.—The causative microbe was first described by Schenk in 1898. Two varieties, *Sporotrichum schenki* and *S. beurmanni*, were originally described, but are now generally regarded as identical. The organisms occur in pus as oval or fusiform spores, and grow in culture as a colourless branching septate mycelium, with clusters of brown fusiform spores on the ends of the filaments. Occasionally the spores are arranged round the filaments. They stain well with the aniline dyes, but irregularly with Gram's stain. Growth occurs under aerobic conditions only, and on ordinary laboratory media. Cultures are best made from closed lesions, which should be punctured with a wide-bore needle, and the material aspirated should be thickly sown on glucose agar plates, which should be kept at laboratory temperature. The colonies, which appear in from 4 to 10 days, are very characteristic. At first white, thick and leathery, they later become convoluted and coffee coloured, and still later may become black. Laboratory animals, especially mice and rats, are susceptible to the lesions resembling those in man, but the disease is seldom fatal. The serum of infected individuals agglutinates the spores of the organism, and specific immunobodies can be demonstrated by complement-fixation tests.

Symptoms and Diagnosis and Treatment—See p 1239

ASPERGILLOSIS

Infections with aspergillus, usually *A. niger* or *A. fumigatus*, have been observed in the middle ear, on abraded corneæ and in the lung. These organisms grow on ordinary laboratory media and related species frequently occur as contaminants.

Cases of lung infection are not very rare (see p 1039). They resemble cases of chronic pulmonary tuberculosis very closely, indeed, they are generally mistaken for this disease until investigation of the sputa reveals their true character.

R. BODLEY SCOTT

MYCETOMA

Synonyms—Madura Foot, Maduramycosis

Definition—A chronic granulomatous condition affecting especially the feet, characterised by marked swelling and the appearance of external nodules connected with deeper sinuses which exude oily, purulent fluid containing various coloured fungoid granules.

Ætiology—The disease is endemic in certain parts of India especially in the Madras Presidency (Madura) but it also occurs in Ceylon, Madagascar, parts of Northern Africa, Cochinchina, Senegambia, the United States, West Indies, South America, New Guinea and elsewhere. It is found in country districts and generally attacks those who go barefooted, the mycetoma fungus probably gaining access through thorn punctures, small cuts or abrasions. Males are more commonly affected than

females. The disease is especially prevalent in the third and fourth decades of life, being generally confined to natives. Many different fungi which have the capacity to produce grains composed of hyphæ in animal tissues have been described as causing mycetoma. Laveran divided them into two groups: (1) the Actinomycoses, caused by fungi of the genera Actinomyces and Nocardia, (2) the Maduramycoses, caused by true fungi, the most important of which is the genus *Madurella*. White, red and black varieties of mycetoma occur clinically.

Pathology.—On section through the softened, jelly-like tissue, sinuses and cystic dilatations communicate with external nodules and internal granulomatous infiltrations which ultimately implicate muscle, fascia and bones, forming a honeycombed cheesy mass. Both the cysts and sinuses are filled with whitish-yellow, red or black granules like fish's roe, which microscopically show thin Gram-positive branching mycelium and peripheral, club-like swellings. Section shows fungoid granules surrounded by mononuclear and leucocytic infiltrations and by fibrous-tissue cells. Sometimes giant cells are evident.

Symptoms.—The incubation period is not definitely known, but in about 50 per cent. of cases there is a history of trauma; many weeks or months may elapse before local lesions develop. The first signs are the presence of one or more hard, painless, subcutaneous nodules, which are about 0.5 to 1 cm. in diameter and generally involve the sole of the foot, and more rarely the hands, face and limbs. Unlike actinomycosis the glands and viscera are never affected, adenitis if present, being due to secondary bacterial infection. After several months swelling increases, the nodules break down and ulcerate, sinuses are formed and discharge their characteristic contents. Finally, the parts become riddled with sinuses, exuding foul-smelling, semi-purulent fluid. The foot becomes more and more swollen and distorted, but it shows little tendency to pain or hæmorrhage. In the early stages the general health is not adversely affected, but later anaemia and cachexia develop if secondary bacterial infection supervenes. Radiograms reveal involvement of the small bones of the feet or hands; both destructive and proliferative reactions are present.

Diagnosis.—This is readily made by finding the characteristic fungi in the pus, but the identification of the actual species of mycetoma requires detailed laboratory investigation.

Prognosis.—There is no tendency to natural cure, and if untreated the prognosis is bad, the patient generally dying from intercurrent disease or secondary infection within 15 years of onset.

Treatment.—**PROPHYLACTIC.**—Protection of exposed parts, like the feet, from thorns and similar trauma appears to lessen the tendency to this disease. Walking barefooted is to be avoided.

CURATIVE.—Sulphonamide therapy combined with surgery is the only satisfactory treatment. In the early stages curettage, or local excision of the nodules with the electric cautery may prove successful. In sinus-riddled feet amputation is almost always necessary but this should not be done until sulphonamides have been well tried.

TORULOSIS

Synonyms.—Cryptococcosis; European blastomycosis.

Definition.—A subacute or chronic infection produced by a yeast-like organism, *Torula histolytica* (*Cryptococcus neoformans*), possessing a special affinity for the cerebrospinal system and lungs.

Ætiology.—The disease affects both men and women and has a widespread geographical distribution. Species of the genus *Torula* reproduce only by budding without mycelial or endospore formations; in pus and cerebrospinal fluid they appear as ovoid or spherical structures, measuring 3μ to 15μ , with definite cell walls

(Jacobson) This infection is a true blastomycosis, since it shows budding in the tissues, but it is not limited to Europe

Pathology—Chronic leptomeningitis may be present, while the brain shows tubercles and gelatinous cyst-like structures in which toruli abound. Clear spaces containing gelatinous material are found round the parasites in the tissues, and this constant finding led Stoddard and Cutler to name the parasites *Torula histolytica*. Similar lesions may occur in the lung, which may be honeycombed, the interstices being filled with gelatinous material

Symptoms—Occasionally localised torulosis involves the skin or mucous membranes, lymph glands, etc., but much more commonly the central nervous system or lungs are implicated. Pulmonary torulosis may involve one or both lungs and gives rise to mild fever, and cough with or without sputum which is mucoid and rarely blood tinged. Dullness and altered breath sounds are generally demonstrable and radiograms often reveal dense shadows resembling neoplasm or massive tubercular infiltration. Meningitic torulosis may have a gradual or sudden onset, early symptoms being headache, vomiting and pain and stiffness in the muscles of the neck. Apathy, depression, irritability and delirium follow. The signs are those of a subacute or chronic meningitis with papillædema. Death occurs with coma and respiratory failure

Diagnosis—The skin and gland lesions are diagnosed by biopsy or culture or blood agar or Sabouraud's medium at room temperature. The pulmonary lesion has to be differentiated from tuberculosis. Other mycotic infections and new growths involving the central nervous system may simulate tuberculous meningitis. Brain tumour or abscess, encephalitis and other mycoses involving the meninges. The cerebrospinal fluid which may be clear, xanthochromic or turbid is under increased pressure and contains an excess of lymphocytes and globulin and a normal or decreased quantity of sugar. The diagnosis is made by culture or finding *Torula histolytica* in the sputum or cerebrospinal fluid where the toruli appear as ovoid or spherical structures measuring 3μ to 15μ with definite cell walls

Prognosis—The course of the disease is subacute or chronic, lasting a few weeks to 2 years with an average duration of $4\frac{1}{2}$ months. In localised infections the outlook is fairly good, but systemic torulosis is practically always fatal

Treatment—Surgical resection with the cautery followed by radiotherapy is the treatment for local lesions. In generalised infections sulphonamide therapy is worthy of trial combined with repeated lumbar puncture to decrease cerebrospinal fluid pressure where the central nervous system is involved

NORTH AMERICAN BLASTOMYCOSIS

Synonyms—Gilchrist's Disease, Chicago Disease

Definition—A term applied to certain chronic granulomatous lesions of the skin or viscera, caused by yeast like blastomycetes

Ætiology—People of any age are susceptible but males in the industrial classes are most often affected. The disease was especially prevalent in Chicago, but is now known to occur in Canada, England and elsewhere. It is caused by *Blastomyces dermatitidis*, which occurs in the tissues as a round, budding yeast like fungus but which produces aerial hyphae on culture. In this respect it differs from torulosis which retains its yeast like characteristics on culture

Pathology—Nodules gummata, papillomata and ulcerations may be produced in the skin and tumour like granulomata and abscesses in the viscera. The pathological lesions resemble the tissue reactions induced by the tubercle bacillus but central necrosis is less and yeast like organisms are present

Symptoms—The clinical manifestations are very variable. Jacobson divides

the primary cutaneous manifestations into papulo ulcerative, papillomatous and gummatous types cutaneous lesions secondary to systemic blastomycosis consist of superficial ulcers with granulating bases which exude pus or form crusts Local pain and discomfort are produced

In systemic blastomycosis the clinical picture resembles a subacute or chronic pyemia, and almost any organ may be involved, the lung (95 per cent) and kidneys (30 per cent) are most frequently implicated producing localising features resembling pleurisy or pneumonia on the one hand and nephritis on the other Osseous involvement and blastomycotic meningitis may also occur

Diagnosis—This depends on the demonstration of blastomyces in pus, sputum or cerebrospinal fluid, moist specimens are prepared by mixing with a drop of sodium hydroxide (10 to 30 per cent) and examined microscopically, when the round or oval, highly refractile bodies (5μ to 20μ) surrounded by a hyaline capsule, may be observed They may also be cultured on glucose agar

Prognosis—Cases with localised cutaneous lesions as a rule ultimately recover if properly treated, but in systemic blastomycosis 90 per cent of cases end fatally in a few weeks to 3 years Cerebrospinal cases invariably die

Treatment—Skin lesions should be radically treated by complete resection with the cautery, or curetted and cauterised Radium and radiotherapy combined with full doses of iodide, i.e. grains 20 to 60 three times a day, are sometimes successful Patients with systemic blastomycosis should receive large amounts of iodide A skin test should be made with 0.1 ml of a standardised heat-killed blastomyces vaccine before starting either potassium iodide or radiation in order to determine hypersensitivity If at 24 and 48 hours the erythematous reaction is less than 1 cm in diameter it is safe to give iodides or radiation If the reaction exceeds 1 cm the patient should be desensitised by the subcutaneous injection with gradually increasing amounts of vaccine

SOUTH AMERICAN BLASTOMYCOSIS

Synonyms—Paracoccidioidal granuloma

Definition—A chronic granulomatous disease of the skin, lymphatic glands mucous membranes and viscera which occurs in South America and is produced by *Blastomyces brasiliensis*

Etiology—The fungus, *B. brasiliensis*, differs from *B. dermatitidis*, the cause of North American blastomycosis, in that it produces multiple budding forms in the tissues instead of single budding forms Some authorities say there are three different species which can cause blastomycosis in South America but as only minor differences have been found it is reasonable to regard them as varieties of the same species The infection is more prevalent in the third decade of life and is much more frequent in males than females The method of infection is unknown

Pathology—Abscesses may occur in which polymorphonuclear reaction is pre dominant, while elsewhere lesions with caseous centres are encountered, the peripheral zone is composed of giant cells, macrophages, lymphocytes and fibroblasts There is frequently extensive intestinal ulceration involving lymphoid tissue as well as nodules in the liver, spleen and kidneys

Symptoms—The cutaneous and systemic clinical manifestations are similar to those encountered in North American blastomycosis South American workers recognise the (1) cutaneous type characterised by skin and mucosal lesions which are common in the region of the mouth and nose, (2) lymphatic type involving the cervical and axillary glands, (3) visceral type with lesions of the abdominal viscera and intestine and (4) mixed type in which a variety or all of these lesions may be found

Diagnosis—The cutaneous lymphatic and visceral types may simulate a variety

of infections particularly those caused by tuberculosis, syphilis, yaws, leishmaniasis and certain other mycoses. The diagnosis is made in the laboratory by the isolation of *B. brasiliensis*.

Prognosis—This disease is almost invariably fatal.

Treatment—Iodides have been reported as causing improvement in early cases, but as in North American blastomycosis harmful effects may result in hypersensitive patients before iodides are given. Certain of the sulphonamides have been reported on favourably but their value needs confirmation.

COCCIDIOIDOSIS

Synonyms—California Disease, Coccidioidal Granuloma, Coccidioidomycosis.

Definition—An acute, subacute or chronic disease, characterised by granuloma formation in the skin or viscera, caused by *Coccidioides immitis*.

Ætiology—The disease is endemic in certain parts of North America and affects persons of any age. Males of the working class are particularly prone. The causative agent is *C. immitis*, which is inhaled in dust in endemic areas, and appears in the tissues or pus as a spherical, double contoured body measuring 20μ to 80μ , which is filled with small endospores (2μ to 5μ). The fungus is readily cultured and laboratory animals are susceptible.

Pathology—The lesions are those of an infectious granuloma, and the tissue changes include tubercles, caseation, necrosis, abscess formation, cavitation, fibrosis and even calcification.

Symptoms—Primary pulmonary coccidioidosis is often subclinical as proved later by positive coccidioidosis skin tests, and the symptoms are generally those of a mild upper respiratory tract infection with dry cough and slight temperature. Others have rigors, night sweats, backache, headache and mucopurulent sputum. About 80 per cent of patients show radiological changes in the lungs. Only 1 in 500 cases of primary pulmonary infection is said to develop the fatal form of the disease. Primary cutaneous coccidioidosis frequently occurs on exposed surfaces manifesting itself as nodular lesions which ulcerate and later become papillomatous. Gummatous-like ulcers and abscesses containing thick mucoid pus may be found in the subcutaneous tissues. A scrofulodermic type of lesion involving the superficial lymph glands especially of the neck, is also recognised. The progressive type of coccidioidosis terminates within a few months to a year or more. Fever continues, dyspnoea and cyanosis develop and the pulmonary physical signs increase. Later progressive involvement of the skin, bones, joints, internal organs, brain and meninges may follow and death ensues within a few weeks. Meningitis is found in 25 per cent of the fatal cases.

Diagnosis—Numerous diseases, including tuberculosis, syphilis, blastomycosis, sporotrichosis, mycetoma and bacterial osteomyelitis may be simulated. Diagnosis essentially depends on isolating *C. immitis* from pathological exudates. Radiograms are of assistance where bone lesions supervene or pulmonary involvement is progressive.

Prognosis—The prognosis is good in primary pulmonary coccidioidosis resolving within 1 month as well as in the cutaneous and glandular types of primary infection. If the pulmonary infection persists 5 or 6 weeks or longer the acute progressive form of the disease should be suspected. In the meningitic type or where the internal organs are involved the prognosis is grave.

Treatment—Patients with primary pulmonary coccidioidosis should be kept in bed until they are afebrile, the sedimentation and leucocyte counts are normal and physical and radiological examination of the lungs satisfactory. Occasionally artificial pneumothorax may be necessary. Radiotherapy may be useful in the treatment of the local lesions. Every effort should be made to build up the resistance of the

patient by good nursing, bed rest and a well-balanced diet reinforced with vitamins, while in acute progressive coccidioidosis desensitisation with progressively increasing doses of coccidioidal vaccine should be attempted and intramuscular injection of colloidal copper (5 ml.) given every 8 to 14 days, the interval being determined by the local and constitutional reaction (Jacobson).

RHINOSPORIDIOSIS

Definition.—A chronic disease due to *Rhinosporidium seeberi* (Wernicke, 1903), which produces friable pedunculated polyps; mucous membranes of the nose, eyes, ears and larynx may be implicated and occasionally the penis, rectum and vagina.

Ætiology.—The disease is most common in children and young adult males. It is especially common in India and Ceylon, where the disease is endemic, but it also occurs in Cochin-China, Malaya, North and South America and England. The infecting spore which has not been cultured is a round body of 6μ to 7μ in diameter, with a chitinous wall, a nucleus and a karyosome. Multiplication by fission occurs, and sporangia or large cysts ultimately lined by cellulose with a diameter of up to 300μ are formed. It is believed that these spores which may number up to 16,000, escape by rupture of the sporangium at the "pore", invade the tissues and repeat the life cycle there; the disease, however, has never been transmitted directly to animals or man. Rhinosporidiosis also occurs in horses, mules and cows, but it is thought to be primarily a disease of fish. In India sand divers are reported to be frequently infected, and it occurs in individuals who dive and swim in stagnant water.

Pathology.—The polyps are soft and nodular and under the surface opaque greyish-white areas occur, which are found on microscopic examination to be large sporangia containing innumerable spores. Chronic inflammation, with plasma cells and lymphocytes, is commonly found but when the spores escape into the tissues, tissue necrosis and acute inflammatory reaction, with the formation of pus sometimes may result; secondary bacterial infection should be suspected under such circumstances.

Symptoms.—A history of nasal symptoms over years may be obtained. Painless itching sensations and profuse mucoid discharge may be the first symptoms. Bleeding is rare unless produced by trauma. The polyps are soft and vascular, sessile at first and later pedunculated; as they enlarge they may protrude through the nares anteriorly or into the pharynx posteriorly. Nasal obstruction, dyspnoea and dysphagia may follow. Polypi may also involve the cheeks, conjunctiva, lacrimal sac or ear. The early lesions on the penis resemble venereal warts and infections of the vagina and rectum may produce lesions resembling rectal polypi, hæmorrhoids or condylomata.

Diagnosis.—The presence of papillomatous polyps composed of granulomatous tissue on the mucous surfaces should suggest the possibility of rhinosporidiosis in doubtful cases. The diagnosis is established by biopsy, microscopic examination revealing the characteristic sporangia.

Prognosis.—The disease is rarely fatal and only causes serious symptoms when the polyps become so large as to result in obstruction of the nose, larynx or œsophagus, or are secondarily infected with bacteria. Smaller lesions sometimes disappear spontaneously after 10 years.

Treatment.—The old practice of removing polyps by a wire snare has been discontinued because of the danger of spreading the infection locally and bacterial complications (Wright). The early lesions may be removed by careful dissection and in advanced cases extensive excision may be necessary, followed by cauterisation. Favourable results have been reported with Neostibosan given intravenously in doses of 0.3 g. for 10 days, especially when combined with surgical treatment.

N. HAMILTON FAIRLEY.

D SPIROCHÆTAL INFECTIONS

SYPHILIS

Definition—A specific disease due to entry of a micro-organism (*Spirochæta pallida* or *Treponema pallidum*) into the tissues, either by inoculation into the skin or mucous membrane, or by needle puncture into veins or other deeper tissues (acquired syphilis) or by transmission *in utero* (congenital syphilis)

Acquired syphilis, unless conveyed by transfusion, or other needle puncture, commonly presents as a primary sore or so-called syphilitic chancre developing at each site of inoculation, which may be followed after a few weeks by a succession of lesions of the skin, mucous membranes, subcutaneous tissues, arteries, muscles, bones, viscera and central nervous system. These may recur again and again at varying intervals throughout the patient's life. Degeneration of the parenchyma of the brain (general paralysis) or of the spinal cord (tabes dorsalis) may develop as late manifestations. From an early stage changes in the blood serum can be detected by various serological tests. Any or all manifestations, including the primary, may be omitted or go unrecognised. With congenital syphilis and syphilis acquired by transfusion the systemic disease is the first manifestation.

Ætiology.—The specific micro-organism was discovered by Schaudinn and Hoffmann in 1905 and called by them *Spirochæta pallida*. Subsequently the organism was renamed *Treponema pallidum*, but many prefer to use the original name *T. pallidum*. It is a minute organism which in fresh specimens under dark-ground illumination appears as a bluish-white, very delicate corkscrew. Its length varies from 5 to 24 μ (average 8 to 10 μ), the distance between individual coils is 1 μ , and the depth of each coil is 1 μ . It is very active in its own ground but slow in moving through the microscopic field. It alternately contracts and expands its coils, bends into loops or forms itself into a right angle. It has been demonstrated in every affected tissue, including the brains of general paralytics. It has a life of only a few hours under natural conditions outside the body, but in blood obtained for purposes of transfusion it can remain alive for 72 hours. It is killed at once by drying, by comparatively low degrees of heat and by much weaker antiseptics than suffice to destroy ordinary pathogenic organisms.

The usual methods of transmission are by sexual intercourse and by way of the placenta to the fetus *in utero*. It does not seem necessary for a person transmitting the disease by intercourse to be suffering at the time from syphilitic lesions of the external genitals, but whether the semen contains the micro-organism in the absence of infectious lesions of the genital mucosæ is a matter of dispute. The period during which a person suffering from syphilis is liable to convey the disease by sexual intercourse varies, after the second year infectivity diminishes, and it is unusual for infection to be transmitted sexually after the fifth year. In the case of the fetus however, although the mother is most dangerous in the first 5 years of her infection, transmission may occur much later, and there is, possibly, no limit to the duration of potential infectiousness. Transmission occurs most often in the second half of pregnancy. Accidental infection usually results from contamination of a minute abrasion with secretion from infectious syphilitic lesions, of which the most dangerous are the primary sore, the moist secondary lesions and some of the early lesions of congenital syphilis. The dangers of accidental infection from later or tertiary syphilides are extremely slight, but it is possible to infect susceptible animals with material from these lesions. Even in the earlier stages the risks of accidental infection appear to be slight, presumably because the organism is so susceptible to external agencies. This is shown by the fact that, even when the disease has been highly

prevalent, the proportion of extragenital syphilitic chancres has been low in countries where the standards of personal hygiene are equal to those of Western Europe. A number of instances of infection by transfusion of blood have been recorded, and they have included cases in which the donor was still in the incubation stage of the disease. On the other hand tertiary syphilitics have been used as donors in cases of emergency in a number of instances without harm to the recipients, and it is clear that the older the infection the less likely is the micro organism to be in the blood stream.

Pathology—Kolle and Evers showed that, after inoculation by scarification, the micro organism reached the nearest lymphatic glands of a rabbit in half an hour. The syphilitic lesion of every stage is histologically the same—a granuloma composed of a collection of epithelioid cells, plasma cells, very numerous small lymphocytes and some giant cells with obliterative endarteritis of the vessels. The pathology of syphilis as it affects the nervous and cardiovascular systems is discussed in the sections dealing with those parts of the body. Here it may suffice to sketch the main general effects of syphilis on the vessels, since they cause a large proportion of the serious results of syphilitic infection. A common result of syphilitic arteritis of smaller vessels is obliteration of the vessel, with important effects resulting from diminution or loss of blood supply. In the primary stage the effect is to produce necrosis of the surface tissue of the sore with "erosion" or ulceration. The epithelium covering the secondary papule is likely to become necrotic and remain adherent as a fine scale, giving the so called "papulo squamous" lesion. The vascular supply is most affected in the gumma or tertiary lesion, leading to necrosis and considerable destruction of tissue. Gummata of bones destroy bony tissue but at the same time provoke a reaction by the periosteum whereby new bone is deposited on the surface of the cortex in irregular fashion and destroyed bone is replaced by densely sclerotic new bone. In the long bones, formation of new bone usually keeps pace with destruction but in the flat bones and particularly those of the skull, destruction is likely to predominate, giving, in neglected cases the appearance of rounded areas of erosion of bone of which the classical example is the *worm eaten skull*. At all stages of syphilis healing is by scar tissue. If the inflammatory infiltrate is small, as in some primary and most secondary lesions the amount of scar tissue is also small. If there is much infiltration, as in some primary lesions and most tertiary lesions the scarring may be considerable. Scar formation and subsequent contraction occasionally has important effects on viscera, interfering seriously with their functions.

It is well known that syphilis is a milder disease in females than in males and experimental evidence suggests that the difference is due to the action of female sex hormones.

Symptoms and Signs—For convenience of description, syphilis is divided into three stages of which the primary consists of the lesions occurring at the sites of inoculation, the secondary of the early generalised lesions and the tertiary of the gummatous and late destructive lesions usually occurring much later after a period of quiescence. Some prefer to classify the lesions affecting primarily the parenchyma of the central nervous system as a fourth or quaternary stage. The division at all stages is only empirical and it is common experience that one stage may merge into or overlap another.

PRIMARY STAGE—The incubation period varies from a minimum of 10 days to a maximum of about 90, with an average of 2 to 4 weeks. A small papule, the *primary chancre* then appears at each site of inoculation, most commonly there is only one lesion, but there may be two or more. The papule quickly enlarges to a round or oval lesion of varying size, the surface usually becomes eroded, or perhaps more deeply ulcerated, the eroded area is clean and granular and surrounded by a dull-red areola varying in width from half to 2 or 3 mm. Beyond the confines of the eroded area the tissues are infiltrated, giving a feeling of thickening or induration

when the base of the lesion is palpated between finger and thumb. This induration on account of which the name of *hard chancre* has been given to the lesion, may become more and more pronounced until in some cases it feels as though there were a button embedded in the tissues. The sore does not bleed easily when scraped but serum oozes freely from it, and this serum usually teems with syphilitic organisms. The sore is comparatively painless.

Individual features vary with the site. Thus, the most indurated primary chancres are those on the mucous surface and edge of the prepuce in males, and on the labia posterior commissure and *portio uteri* in females. In the case of a sore at the reflection of the prepuce on to the *corona glandis*, when the prepuce is retracted the lesion may flick over like the tarsal plate when the upper eyelid is everted. A sore at the edge of the prepuce may convert the preputial orifice into a fibrous ring. Induration is easily felt in a sore affecting one wall of the *fossa navicularis*, which then feels as though a solid object were embedded in it. With primary sores of the *glans penis* induration is difficult to appreciate because of tightness of the tissues, but the sore is easy to recognise by its dull-red areola, even contour, eroded centre and indolent progress. Rarely, a primary sore has been found deep in the urethra, and the diagnosis has been made by urethroscopic examination together with the discovery of *T. pallidum* in the scanty urethral discharge. Primary chancres of the skin are dusky red and indurated. They may be covered with a reddish-black scab due to dried secretion containing altered blood. Ulceration is usually more marked in sores affecting the under surface of the prepuce, the skin at the peno scrotal angle, the perionychia, tissues, the lips and the tonsils. Almost all primary sores are comparatively painless but when related to a nail of finger or thumb they may be exquisitely painful, and thus may be mistaken for whitlows. The primary sore affecting the prepuce, the skin of the penis or, especially, the female labia may be accompanied by an indurated œdema of the affected parts, which may become rather livid in appearance, the same condition may affect the uterine cervix. This is sometimes called cold œdema.

The course of the primary syphilitic sore varies greatly. In some cases the lesion is fleeting, and its apparent triviality may lead to failure to seek advice, the history of a substantial proportion of cases of late syphilis is that the initial lesion was either unnoticed or was very trivial. Ordinarily, the primary sore which remains untreated lasts for a month or longer, and, after the erosion has healed over, a button of indurated tissue may remain to mark the site. Weeks or months after healing, the sore may break down again, syphilitic organisms have been found by histological examination of the scars of such lesions many years later. When a syphilitic chancre is infected by secondary organisms, ulceration may be more severe, and in rare instances the area becomes phagedenic. In such cases the surrounding tissues very rapidly become black and necrotic, and large parts of the external genitalia may be destroyed.

Shortly after the appearance of the primary sore the nearest lymphatic glands often become painlessly enlarged, the *indolent bubo*, and the lymphatics running from a sore on the penis can sometimes be felt beneath the skin. The affected glands may reach a large size, bulging under the overlying skin which, however, does not become reddened. The glands are of firm, rubbery consistency and remain discrete, or distinguishable one from another. The character of the swelling and the absence of signs of acute inflammation often give the clue to the nature of the causative lesion. In females the inguinal lymphatic glands remain unaffected if the sore is deeply situated. Syphilitic buboes do not usually suppurate, but may do so if the sore has become contaminated by secondary organisms, so that the presence of suppuration should not weigh heavily against a diagnosis of syphilis. Some time after the local lymphatic glands have begun to enlarge and before other signs of secondary syphilis can be found, there may be widespread adenitis, which can be appreciated by palpation, particularly of the cervical, axillary and epitrochlear glands.

When the sore is about 15 days old, the blood serum commonly gives positive

Wassermann and other serological reactions, such as the Kahn, Kline, Meinicke and Price. These tests employ antigens made from crude alcoholic extracts of heart muscle. Recently, the purified active principle of these extracts, *cardiolipin*, has been isolated and is employed in conjunction with lecithin and cholesterol for various complement fixation tests or for flocculation tests such as the V D R L reaction (Venereal Disease Research Laboratory). The percentage of cases in which positive results to the serological tests are given increases with the duration of the disease until the outbreak of lesions of the skin characteristic of the next or secondary stage. Practically 100 per cent of patients in the secondary stage have positive serological tests.

SECONDARY STAGE—In general the skin eruptions of secondary syphilis tend to be widespread, non-irritant, discrete, polymorphic, symmetrically distributed, dull red in colour, rounded in outline and infiltrative to touch.

Commonly, a generalised pink macular rash, the *macular or roseolar rash*, appears 4 to 8 weeks after the sore. It usually appears on the sides of the trunk as pinkish spots, varying in size from a split-pea to a finger nail, which with age may deepen in colour to a dull red. At first they may be difficult to see, but they become more obvious after the patient has been stripped for a few minutes. The eruption spreads gradually over the trunk and limbs, missing the face except perhaps for slight mottling of the chin, and fades in a few weeks, leaving little or no staining.

After the fading of the first roseola, a patchy loss of pigment may occur, especially in the pigmented zone of the necks of brunettes. The depigmented areas are circular and each about the area of a finger-tip. The condition has been called *syphilitic leucoderma or collar of Venus*. It is a residual effect which may persist indefinitely.

The *papular* eruption follows closely after the roseolar, and takes a number of different forms, the commonest and usually the earliest being dome shaped, rounded, dull-red papules distributed over the trunk, limbs and face. Most are about the size of a lentil, but amongst the smaller papules may be larger ones, sometimes even the size of a silver threepence. The papules are discrete and symmetrically distributed. On palpation with the tips of the fingers they feel indurated. Variations of the ordinary, papular eruption are the papulo-squamous, squamous, papulo-pustular and pustular. In the *papulo squamous* a large proportion of the papules are covered at their centres by loose scales. The *squamous* syphilide is a papular eruption in which scaling is a still more prominent feature. In the *papulo pustular* syphilide the centre of the papule becomes necrotic, and looks rather like an acne spot. When the whole papule breaks down, a *pustular* syphilide results and in the aggregate may resemble a varicellar or a variolar eruption. A more severe form is the *ecthymatous* type in which the papule breaks down quickly, and the underlying tissues become eroded or ulcerated. As the destruction of tissue extends, the secretion dries to a crust. This may become heaped up by a deposit of successive layers with the formation of limpet-like crusts, blackish or greenish in colour due to altered blood, a condition which is called *rupia*.

Variations of the papular syphilide in different situations—Round the anus, between the buttocks, on the lateral surfaces of the scrotum, on the labia, on the inner aspects of the upper thighs and in other warm moist areas of the body, the papular syphilide often becomes large and prominent, forming fleshy looking masses, rounded in outline, with broad base and flat top. The surface may become greyish white, due to necrosis, and exude serum packed with *T pallidum*. These are the *broad condylomata condylomata lata* or moist papules, the most infectious lesions of syphilis. They tend to become confluent and, after necrotic tissue is shed from the surface, to present a moist, dull-red, eroded surface fringed with loose epithelium. They are occasionally found between the toes under pendulous mammae and in other unexpected situations.

On the palms and soles the papules appear as flat or slightly raised spots, varying in size from a split-pea to a sixpence. They scale easily, leaving collars of loosened

epithelium surrounding shining papules The finger nails may show characteristic changes, more especially in the later secondary stage The ends of the fingers become pinkish red and bulbous, and at the reflection of the skin on the nail are weeping granulations The nail becomes brittle and lustreless and is shed The papular syphilide may be well marked on the forehead following the margin of the hair, the so called *corona veneris*, and it is often possible to find many papules in the hairy scalp On other parts of the face, especially about the naso-labial folds and the chin, the papules are sometimes set in rings, *annular syphilides* In some cases the facial lesions may be hypertrophic, especially at muco-cutaneous junctions, appearing like condylomata lata, on account of a resemblance to surface lesions of yaws, the condition has been called a *framboesiform syphilide*

The small *follicular syphilide* usually appears later than the early papular eruption. Each lesion is related to a hair follicle and they are found in small clusters of minute dusky-red papules on the trunk, particularly the back Only in pigmented skins are these lesions found in considerable numbers The *lichenoid syphilide*, also a late secondary manifestation, occurs as a small, flat, dull red elevation, a few millimetres wide and often polyhedral

Recurrent papular eruptions—Recurrences of the papular eruption tend to be much more limited in distribution A common form, the *corymbose syphilide*, appears as one or only a few rather densely packed groups of papules, the diameter of each group covering 1 to 3 inches or more In some cases there is a large papule in the centre of the group and around it, separated by a zone of healthy skin, is a crowd of smaller papules The chief sites are the extensor surfaces of the arms, the shoulders, back and abdominal wall

The hair is shed to a varying degree in the secondary stage In most cases the thinning is not particularly noticeable, in others there is patchy loss, giving the sides and back of the head a moth eaten appearance, exceptionally the patient may become temporarily bald The beard and eyebrows may participate in these changes.

Lesions of the mouth and throat—Before the rash appears on the body the soft palate may become erythematous Other lesions of the mouth usually make their first appearance with the papular syphilide of the skin On the mucous surfaces of the lips and the pillars of the fauces the early syphilide is a rounded greyish white patch—the so called *mucous patch*—edged with a dull red areola, which marks it off from the surrounding mucous surface The greyish white appearance is due to necrotic tissue On the pillars of the fauces the lesions may become confluent and on separation of the slough, form a serpiginous erosion, sometimes known as the *snail track ulcer* On the tonsil the lesion tends to ulcerate rather deeply If a mucous patch on the lip crosses the angle of the mouth it becomes fissured On the sides of the tongue there may be fissuring and ulceration, and on the under-surface there may be condylomata lata On the dorsum of the tongue the mucous lesions appear as pink, bald spots after the papillæ of the tongue have been shed in the necrotic process The discharge from these lesions teems with syphilitic organisms and is very contagious Mucous patches can also be found in the nose, on the septum and the floor In the larynx by suitable examination, they can be seen chiefly on the

are usually called *mucous erosions*. On the genitalia, especially on the glans, they may be mistaken for primary lesions, especially if other signs of secondary syphilis are absent or inconspicuous.

Lymphadenitis.—Rubbery, discrete, non-tender enlargement of accessible lymphatic glands, especially those of the neck, is very common in the secondary stages of the disease.

Joints and bursæ are not often affected in secondary syphilis, but occasionally effusion occurs. The result is likely to be swelling without pain or great limitation of movement, but in rare instances such effusions are painful, especially at night. The tendon-sheaths may be affected similarly. Aching pains in the long bones—so-called *osteocopic pains*—may result from mild periostitis. The pain may be severe and tends to be worse at night. It is rare to find the objective signs of periostitis at this stage of the disease.

The eye.—Acute *iridocyclitis* of one or both eyes occasionally occurs late in the course of secondary syphilis, but is more common in association with infectious relapse. It may be differentiated from iridocyclitis due to other causes by presence of other evidence of secondary syphilis and by prompt and satisfactory response to antisyphilitic treatment.

Hepatitis, with jaundice and enlargement of the liver, is occasionally found in the secondary stages of syphilis and responds promptly to antisyphilitic treatment.

Epididymitis occurs in a very small percentage of cases, usually in the form of small nodules, varying in size from a pea to a small marble, in the *globus major*.

From about the sixth month, or even earlier, the patient may develop symptoms and signs pointing to syphilitic disease of the *central nervous system*, which are described elsewhere in this volume. It is well to remember that in over 30 per cent. of cases of secondary syphilis changes in the cerebrospinal fluid indicate invasion of the central nervous system, though only a small proportion of these patients show clinical signs of nervous disease; this fact should be borne in mind in testing for cure.

Constitutional Symptoms.—Even in the incubation period, there may be a rigor followed by some degree of fever and pains in the limbs. In some cases, towards the end of the primary stage or on the appearance of the rash, the patient may develop pyrexia which is intermittent, continuous or remittent, and accompanied by some constitutional disturbances, such as headache, malaise, anorexia and loss of weight. In rare cases the fever and constitutional symptoms may be prolonged and severe, and if no rash appears the condition may be very puzzling. The presence of generalised adenopathy should arouse suspicion. Headache may be severe and persistent and may be due to meningeal involvement.

Anæmia.—Moderate degrees of secondary anæmia are common. The red cell count may be slightly reduced, to between 4,000,000 and 5,000,000 with hæmoglobin content as low as 70 per cent. In rare cases the anæmia may be much more severe. In the early stages the total white cells may reach 20,000 per c.mm. but levels of 10,000 to 12,000 are more common. Lymphocytes predominate and may constitute 55 per cent. of the total; this lymphocytosis may persist for months.

TERTIARY STAGE.—There is no sharply dividing line between the secondary and tertiary stages, and late in the secondary or early in the tertiary stage lesions may appear which have features common to both stages. In general the tertiary or gummatous lesions tend to be localised and asymmetrical in distribution and destructive in character.

The gummatous lesions which involve the skin are of three kinds:

(1) *The nodular cutaneous syphilide*.—This appears as a group of small gummata arising in the true skin of one or more isolated areas of the body. The individual nodules are each about the size of a pea, rounded, dull red in colour and firm and elastic on palpation. They often become confluent to form a more or less continuous ridge, arranged in roughly concentric circles, or arcs of circles, or as a snake-like line

of varying length. The affected area is very often one that is exposed to injury or constant friction; it may be as small as a finger-nail or larger than a hand. The individual gummata may degenerate only so slightly as to produce some scaling, or may ulcerate more deeply and become crusted. The lesion extends centrifugally by the development of more gummata, and leaves in its wake an area of skin which may appear normal, or may be pigmented or, if the nodules have ulcerated, may show supple, papery scars, following the concentric distribution of the lesion. In some cases with ulceration, extension is more rapid than healing, and a large patch of ulcers of the skin may be left behind the advancing line of involvement. Sometimes the nodules do not resolve as the lesion extends and dull-red rounded or polycyclic plaques of indurated tissue are formed. These become covered with greyish waxy-looking crusts and the condition has therefore been named:

(2) *The squamous tertiary syphilide*.—The lesions often resemble those of psoriasis and have been called on that account *psoriasiform tertiary syphilides*. The commonest tertiary lesion to involve the skin is

(3) *The subcutaneous gumma* which commences in the subcutaneous or deeper tissue, such as muscle or periosteum of bone, and presents as an indolent rounded subcutaneous swelling of rubbery consistency. The swelling is painless and, at first, the skin over it is not discoloured; when first noticed it may be no more than a small nodule but may slowly increase in size to that of an orange. In due course the expanding swelling is likely to become attached to the overlying skin which then shows dull-red discoloration. The central area of skin then becomes involved in the necrotic process and breaks down with the formation of a sinus which develops into a gummatous ulcer. This is highly typical in appearance. It is circular in outline, following the contour of the original swelling, or polycyclic if confluence of two or more gummata has occurred. The ulcer is sharply punched out with vertical walls leading down to a granular floor covered with clean dull-red granulations. A tough yellowish-white slough, the so-called *wash leather slough*, may remain adherent to walls and floor. The skin surrounding the margin of the ulcer shows dull-red discoloration and squamous change. If the gummatous process commences in or subsequently involves the periosteum of bone, the floor of the ulcer consists of necrotic bone. The regional lymphatic glands are not involved. On healing, the non-contractile "tissue paper" scars show the rounded outline of the original lesion.

The mucous membranes of the *mouth and throat* are often involved in the tertiary stage of syphilis. The process usually commences in submucous tissue or in deeper structures, such as the periosteum of the hard palate or the musculature of the tongue. The soft palate and uvula are particularly common sites and ulceration is likely to cause perforation and subsequent deformity. Sometimes the soft palate becomes adherent to the posterior pharyngeal wall. Perforation of the hard palate may result from gummata commencing in the roof of the mouth or in the floor of the nose. Ulceration of the tonsil may be deeply destructive. These conditions are remarkable for their chronicity and for the fact that they produce discomfort rather than pain.

In the *tongue* discrete gummata may reach the surface and cause deeply punched-out ulcers, but more commonly the process is a diffuse gummatous infiltration following the distribution of the vascular supply. In the initial stages the tongue is swollen, but on healing diffuse fibrosis occurs with subsequent contracture and the tongue may become smaller than normal. At the same time characteristic changes may appear on the surface of the tongue, giving the appearance known as *chronic superficial glossitis*. The changes are three in number, and one or any combination of them may be present. Firstly, contraction of fibrous tissue may produce deep irregular fissuring of the surface of the tongue. Secondly, interference with the blood supply of the mucous membrane renders it abnormally vulnerable to minor injury which causes patchy necrosis of superficial epithelium with irregular white areas of adherent

dead epithelium, particularly at the margins of the tongue, the condition known as *leucoplakia*. Similar patches may be found on the mucous surfaces of the cheeks at the angles of the mouth. Thirdly, the patches of leucoplakia are apt to separate at the margin of the tongue carrying away the papillae and leaving smooth glazed areas. The patient may complain of pain in the tongue and may be sensitive to acids, spices and hot foods. The condition may, however, be symptomless. Discomfort and pain are usually relieved by antisyphilitic treatment but the changes in the tongue are permanent. Carcinomatous change is common.

In the *larynx* submucous gummata are common and, on laryngoscopy, may be seen as small rounded swellings above the vocal cords. Deeply destructive ulceration may follow and there may be actual sloughing of laryngeal cartilages. In the early stages there are alterations of voice and later, in neglected cases, stenosis may follow.

Tertiary syphilis of *bones* causes variable symptoms and signs, and may be difficult to diagnose unless the possibility of such infection is remembered. The bones most commonly affected are the tibia, the bones of the skull, the clavicle, sternum and femur, but no bone is immune and trauma is frequently a predisposing cause. There may be no symptoms or the patient may complain of pain at the affected site—a gnawing, persistent pain of boring character which is worse at night. If the bone is near the surface an irregular hard swelling may have been noticed. In long bones the process is likely to involve a limited segment of the bone giving rise to an irregular hard swelling as the result of subperiosteal deposits of new bone. Radiologically the new bone formation can be seen on the surface of the original cortex and the cortical bone is seen to be sclerotic with, perhaps, some invasion of the medullary cavity. In the flat bones, and particularly those of the vault of the skull, the process is destructive, with rounded areas of osteoporosis surrounded by areas of moderate sclerosis—so called *worm-eaten skull*. Severe deformities may result when this destructive process involves the nasal bones, the nasal septum and the palate, which are common sites of gummatous lesions. After a period of *ozena* the bridge of the nose may be destroyed or a large perforation suddenly appear in the hard palate. From the nose, the process may spread to the skin with disfiguring ulceration of the face. Syphilitic dactylitis is very uncommon but occasionally causes an indolent painless swelling, usually of the proximal phalanx of a finger. Vertebral gummata are rare but have been known to cause retropharyngeal, lumbar or iliac abscesses.

Gummata of the *liver* are now quite uncommon. The lesions are usually multiple and may grow to a large size and be very destructive. On healing, the liver substance may be intersected by sheets of fibrous tissue which reach the surface, dividing the organ into irregular lobes, *hepar lobatum*. The condition is commonly asymptomatic but irregular enlargement of the liver may be felt and the spleen also may be enlarged. Evidence of portal obstruction is uncommon. Gross secondary anaemia is sometimes associated.

Tertiary syphilis of the *testis* is now quite rare. It may result in diffuse interstitial involvement, with slow painless enlargement of the organ. Testicular sensation is lost. Occasionally localised gummata are found.

The *joints, bursae and tendon sheaths* are not often invaded in tertiary syphilis. The parts affected are those most exposed to stress and strain, such as the knee joint and the pre patellar bursa. The swelling is of soft rubbery consistency and shows no signs of acute inflammation. It follows the outlines of the affected joint, bursa or tendon sheath.

Liver occurs in some cases of tertiary syphilis, and the fact that it is due to the disease may be suggested by its response to antisyphilitic treatment. It has occurred particularly in association with gummatous hepatitis. Syphilis should be remembered as a possible cause in cases of persistent pyrexia of unknown origin.

Diagnosis—**PRIMARY STAGE**—It is axiomatic that every genital sore and every inflammatory sore elsewhere on the body of which the diagnosis is not obvious should

of varying length. The affected area is very often one that is exposed to injury or constant friction, it may be as small as a finger-nail or larger than a hand. The individual gummata may degenerate only so slightly as to produce some scaling, or may ulcerate more deeply and become crusted. The lesion extends centrifugally by the development of more gummata, and leaves in its wake an area of skin which may appear normal, or may be pigmented or, if the nodules have ulcerated, may show supple, papery scars, following the concentric distribution of the lesion. In some cases with ulceration, extension is more rapid than healing, and a large patch of small ulcers of the skin may be left behind the advancing line of involvement. Sometimes the nodules do not resolve as the lesion extends and dull-red rounded or polycyclic plaques of indurated tissue are formed. These become covered with greyish waxy-looking crusts and the condition has therefore been named.

(2) *The squamous tertiary syphilide*—The lesions often resemble those of psoriasis and have been called on that account *psoriasiform tertiary syphilides*. The commonest tertiary lesion to involve the skin is

(3) *The subcutaneous gumma* which commences in the subcutaneous or deeper tissue, such as muscle or periosteum of bone, and presents as an indolent rounded subcutaneous swelling of rubbery consistency. The swelling is painless and, at first, the skin over it is not discoloured, when first noticed it may be no more than a small nodule but may slowly increase in size to that of an orange. In due course the expanding swelling is likely to become attached to the overlying skin which then shows dull-red discoloration. The central area of skin then becomes involved in the necrotic process and breaks down with the formation of a sinus which develops into a gummatous ulcer. This is highly typical in appearance. It is circular in outline, following the contour of the original swelling, or polycyclic if confluence of two or more gummata has occurred. The ulcer is sharply punched out with vertical walls leading down to a granular floor covered with clean dull-red granulations. A tough yellowish-white slough, the so-called *toash leather slough*, may remain adherent to walls and floor. The skin surrounding the margin of the ulcer shows dull-red discoloration and squamous change. If the gummatous process commences in or subsequently involves the periosteum of bone, the floor of the ulcer consists of necrotic bone. The regional lymphatic glands are not involved. On healing, the non-contractile "tissue paper" scars show the rounded outline of the original lesion.

The mucous membranes of the *mouth and throat* are often involved in the tertiary stage of syphilis. The process usually commences in submucous tissue or in deeper structures, such as the periosteum of the hard palate or the musculature of the tongue. The soft palate and uvula are particularly common sites and ulceration is likely to cause perforation and subsequent deformity. Sometimes the soft palate becomes adherent to the posterior pharyngeal wall. Perforation of the hard palate may result from gummata commencing in the roof of the mouth or in the floor of the nose. Ulceration of the tonsil may be deeply destructive. These conditions are remarkable for their chronicity and for the fact that they produce discomfort rather than pain.

In the *tongue* discrete gummata may reach the surface and cause deeply punched out ulcers, but more commonly the process is a diffuse gummatous infiltration following the distribution of the vascular supply. In the initial stages the tongue is swollen, but on healing diffuse fibrosis occurs with subsequent contracture and the tongue may become smaller than normal. At the same time characteristic changes may appear on the surface of the tongue, giving the appearance known as *chronic superficial glossitis*. The changes are three in number, and one or any combination of them may be present. Firstly, contraction of fibrous tissue may produce deep irregular fissuring of the surface of the tongue. Secondly, interference with the blood supply of the mucous membrane renders it abnormally vulnerable to minor injury which causes patchy necrosis of superficial epithelium with irregular white areas of adherent

dead epithelium, particularly at the margins of the tongue, the condition known as *leucoplakia*. Similar patches may be found on the mucous surfaces of the cheeks at the angles of the mouth. Thirdly, the patches of *leucoplakia* are apt to separate at the margin of the tongue carrying away the papillæ and leaving smooth glazed areas. The patient may complain of pain in the tongue and may be sensitive to acids, spices and hot foods. The condition may, however, be symptomless. Discomfort and pain are usually relieved by antisyphilitic treatment but the changes in the tongue are permanent. Carcinomatous change is common.

In the *larynx* submucous gummata are common and, on laryngoscopy, may be seen as small rounded swellings above the vocal cords. Deeply destructive ulceration may follow and there may be actual sloughing of laryngeal cartilages. In the early stages there are alterations of voice and later, in neglected cases, stenosis may follow.

Tertiary syphilis of *bones* causes variable symptoms and signs, and may be difficult to diagnose unless the possibility of such infection is remembered. The bones most commonly affected are the tibia, the bones of the skull, the clavicle, sternum and femur, but no bone is immune and trauma is frequently a predisposing cause. There may be no symptoms or the patient may complain of pain at the affected site—a gnawing, persistent pain of boring character which is worse at night. If the bone is near the surface an irregular hard swelling may have been noticed. In long bones the process is likely to involve a limited segment of the bone giving rise to an irregular hard swelling as the result of subperiosteal deposits of new bone. Radiologically the new bone formation can be seen on the surface of the original cortex and the cortical bone is seen to be sclerotic with, perhaps, some invasion of the medullary cavity. In the flat bones, and particularly those of the vault of the skull, the process is destructive, with rounded areas of osteoporosis surrounded by areas of moderate sclerosis—so-called *worm eaten skull*. Severe deformities may result when this destructive process involves the nasal bones, the nasal septum and the palate, which are common sites of gummatous lesions. After a period of *ozæna* the bridge of the nose may be destroyed or a large perforation suddenly appear in the hard palate. From the nose, the process may spread to the skin with disfiguring ulceration of the face. Syphilitic dactylitis is very uncommon but occasionally causes an indolent painless swelling, usually of the proximal phalanx of a finger. Vertebral gummata are rare but have been known to cause retropharyngeal, lumbar or iliac abscesses.

Gummata of the *liver* are now quite uncommon. The lesions are usually multiple and may grow to a large size and be very destructive. On healing, the liver substance may be intersected by sheets of fibrous tissue which reach the surface, dividing the organ into irregular lobes, *hepar lobatum*. The condition is commonly asymptomatic but irregular enlargement of the liver may be felt and the spleen also may be enlarged. Evidence of portal obstruction is uncommon. Gross secondary *anæmia* is sometimes associated.

Tertiary syphilis of the *testis* is now quite rare. It may result in diffuse interstitial involvement, with slow painless enlargement of the organ. Testicular sensation is lost. Occasionally localised gummata are found.

The *joints, bursæ and tendon sheaths* are not often invaded in tertiary syphilis. The parts affected are those most exposed to stress and strain, such as the knee joint and the pre patellar bursa. The swelling is of soft rubbery consistency and shows no signs of acute inflammation. It follows the outlines of the affected joint, bursa or tendon sheath.

Fever occurs in some cases of tertiary syphilis and the fact that it is due to the disease may be suggested by its response to antisyphilitic treatment. It has occurred particularly in association with gummatous hepatitis. Syphilis should be remembered as a possible cause in cases of persistent pyrexia of unknown origin.

Diagnosis—PRIMARY STAGE.—It is axiomatic that every genital sore and every inflammatory sore elsewhere on the body of which the diagnosis is not obvious should

be examined for *S. pallida*. This should be done before any antiseptics have been applied or antibiotics administered. The sore should first be cleaned with a swab and its edge scraped, or a fairly deep puncture made in its margin with the point of a scalpel or a vaccination lancet. The sore should then be squeezed and the serum collected after it has oozed for a few minutes. When the necessary apparatus is at hand it is better to examine the specimen at once by dark-ground illumination; if it has to be sent away, the serum should be allowed to run into a capillary tube, of which both ends may be sealed with candle grease. Spiral organisms other than *T. pallidum* may be seen in specimens obtained from the genitals or the mouth, but they are largely eliminated by taking care to clean the surface of the lesion before collecting the specimen. Organisms should not be accepted as *T. pallidum* unless they are characteristic in appearance and movement. Alternatively a good method is to puncture the nearest enlarged lymphatic gland and aspirate a little of the gland fluid. A moderately stout bollow needle is inserted obliquely into the gland, and a few minims of sterile normal saline are injected into it. The gland is massaged and aspiration applied by a syringe.

Clinically, primary syphilitic sores are distinguished from others by the long incubation period, comparative painlessness, colour, indolence, surrounding infiltration, slighter tendency to bleed, indolent enlargement of neighbouring lymphatic glands, and the presence of *T. pallidum*. The length of the incubation period is a guide only when the patient has not been exposed to infection for more than 10 days.

Various conditions which are commonly found on the genitalia may give rise to difficulty in diagnosis. Several of the more important require brief mention. *Herpes genitalis* appears as grouped vesicles of pinhead size which break down to small circular erosions. They cause irritation but they are not indurated. *Chancroid* has an incubation period of only a few days; the sore is painful and destructive, and the edges are undermined. Usually there is more than one sore. There may be an accompanying bubo which tends to suppurate and to break down with the formation of a chaneroidal ulcer in the groin. Infection with both syphilis and chancroid occurs sometimes and therefore to exclude the diagnosis of syphilis it is important to repeat the microscopic test at intervals until the sore heals and to test the blood serum at least monthly for 3 months.

Scabietic runs on the glans and skin of the penis are mound-like and not eroded or indurated.

Syphilitic chancres in parts of the body other than the genitals are often overlooked, mainly because the possibility of syphilitic infection is not considered. Unilateral tonsillitis should arouse suspicion, especially if associated with painless enlargement of lymphatic glands in the upper part of the anterior triangle of the neck on the affected side. Similarly, the clue to the nature of a syphilitic chancre on the lip may be given by enlargement of lymphatic glands of the submaxillary group. A primary sore affecting the terminal phalanx of a thumb or finger often simulates a whitlow; the syphilitic sore is more hrawny and more indolent.

SECONDARY STAGE.—The maculo-roseolar syphilide is fairly easy to distinguish by the history of a primary sore with indolent adenitis, by the subcuticular, deeply grounded appearance of the spots, which very rarely itch and are pinkish in colour, and by the association of positive serological reactions. Other erythemata are brighter red and irritable, and often affect the backs of the hands. The ordinary dome-shaped papular syphilide is usually easy to distinguish from a non-syphilitic eruption. The indurated feel of the papule, its shining appearance when pinched, its readiness to scale, its dull-red colour and its association with lesions of the mouth and throat are all valuable diagnostic signs. The different appearances which a papular syphilide presents in different parts of the body, such as dry papules on the trunk and most areas of the limbs and moist papules in the perianal area, on the scrotum, between the toes and in other moist warm parts, contrast strongly with non-syphilitic derma-

toes, which are true to type, wherever situated. *The microscopic test should always be applied to the exudate from the lesion in any doubtful case*, and rarely fails to clinch the diagnosis, even with papulo-pustular or pustular syphilides.

Among the eruptions which may be confused with syphilitic rashes is that of *urticaria pigmentosa*, but with this condition the spots are dark and are not raised, and on rubbing the macule a wheal is formed. The blood serum may give a doubtful or even positive reaction in such a case, but the titre of a quantitative test is considerably lower than that usually given by the blood of a patient with secondary syphilis. *Seborrhœa* is more superficial and is more scaly, the scales being greasy. *Pityriasis rosea* is often mistaken for syphilis, but the lesions are brighter in colour and more irritable; they tend to become annular, with their centres covered by branny scales. *Ringworm* is more superficial and irritable, and the fungus can be found in scrapings from its border. *Tinea cruris* or *dhobie's itch* affects a triangle at the upper and inner part of the thigh; it is brighter red, more irritable and quite superficial. *Drug rashes* are more inflammatory and irritable; they appear more suddenly, and are usually associated with a history that the patient has taken a drug which is known to cause such an eruption. The eruptions of *specific fevers* are usually accompanied by more pronounced constitutional symptoms. *Acne spots* are pustular and show more inflammatory reaction than secondary syphilides and they affect the upper part of the chest and the back between the shoulders, rather than the flanks, loins and limbs. The spots of *molluscum contagiosum* are white and umbilicated, and caseous matter can be squeezed from their centres. *Lichen ruber planus* is characterised by flatter, smaller, polygonal spots of a violet tinge and waxy appearance; it is more irritable. *Psoriasis* is usually superficial, bleeds at a number of points when slightly scraped, and affects the extensor rather than the flexor surfaces of the limbs; the scales are more silvery, and in moist situations the rash remains true to type, contrasting with the syphilide, which becomes the moist papule or broad condyloma. *Varicellar spots* are vesicular at one stage and more superficial and irritable. With *variola* there is a prodromal stage with fever and backache; the spots are of uniform character and appear first on face and wrists. *Pemphigus vegetans* may bear a superficial resemblance to condylomata lata, but no *T. pallidum* can be found in serum from the lesions, and usually typical bullæ can be found elsewhere on the body or limbs. Syphilitic condylomata have sometimes been diagnosed as hæmorrhoids, but they are usually separated from the anal ring by some normal skin. *Condylomata acuminata*, or genital warts, are granular and pedunculated. The deeper forms of pustular syphilide which show considerable crusting, such as the ecthymatous or the rupial, are distinguished from ordinary *impetigo* by the darker colour of the crusts, the circular rather than linear shape of the lesions, and the greater degree of tissue destruction below the crusts. *Scabies* is sometimes mistaken for a crusted syphilide, and the reverse is also true. The individual scabietic lesion is often easy to recognise where it has not been scratched, on the wrists, and between the fingers, but it is well to remember that scabies and syphilis often co-exist.

Secondary syphilitic lesions of the mouth can usually be diagnosed by the characteristics described. *Vincent's angina* is a possible source of error, but the condition is painful and the microscopic findings are characteristic.

TERTIARY STAGE.—An indolent swelling, or an ulcer preceded by a swelling, should always arouse a suspicion of syphilis. Denial of primary sore, or of secondary lesions, is of no importance, for they may never have appeared or have been forgotten long ago. The positive serological reactions may mislead, for by no means all swellings and ulcers in syphilitic patients are themselves syphilitic. On the other hand, negative serological reactions are strong but not absolute evidence against tertiary syphilis. Space does not permit enumeration of the many conditions from which the lesions of tertiary syphilis may have to be diagnosed. An occasional source of error is *epithelioma* in the mouth, which is more apt to be painful than a gumma and to

appear as a lesion with a raised rolled everted edge. The onset of the condition is frequently determined by old syphilitic glossitis and the presence of positive blood serological tests may obscure the diagnosis. *Varicose ulceration* on the legs may have to be diagnosed from gummatous ulceration. The ulcers are usually much less regular in contour, less sharply punched out, and associated with more evidence of acute inflammation and of venous stasis.

Treatment.—PREVENTIVE.—The value of any method of prevention of syphilitic infection has always been difficult to determine. Local cleansing and the use of antiseptics have been recommended and practised for many years, but with any such procedure the failures are obvious enough but the successes are never known. Clearly no method of disinfection is likely to be successful unless it is promptly applied. The genitalia should be washed well with soap and water and then steeped for some minutes in a mercurial solution such as 1 : 2000 mercuric potassium iodide, or 1 : 2000 oxycyanide of mercury. The parts should then be anointed with an ointment, such as Gauducheau's, viz., mercury cyanide, 0·10; thymol, 1·75; calomel, 25·00; lanolin, 50·00; liquid paraffin, 10·00; soft paraffin to 100·00. Some solution of mercury oxycyanide 1 : 4000 may be injected into the urethra after urination. For females washing of the external genitals, followed by inunction with ointment should be practised as for males and should be followed by a vaginal douche with mercurial solution such as 1 : 4000 oxycyanide of mercury. Any prophylactic measure may prevent only the appearance of the chancre and should therefore be followed by blood tests for at least 3 months.

Prophylaxis by ingestion or injection of antisiphilitic remedies should not be practised, because the effect may be to mask the symptoms for many months without curing the patient. Since the introduction of penicillin for the treatment of syphilis a good deal has been said and written about the desirability of abortive treatment of the patient who has taken a risk of contracting syphilis. To give such treatment is tantamount to accepting the diagnosis, and logically, should be followed by observation and testing for at least 2 years with due restrictions as regards marriage and family life. Quite apart from the prolonged anxiety involved there are obvious disadvantages to the patient, who in most cases can be pronounced free from infection with certainty after 3 months.

Accidental infection of fingers, lips and other extra-genital parts is best prevented by avoiding contamination with fresh secretions from patients in the early stages of infection. They should be warned of the risks arising from sharing table utensils, crockery and house linen with others. They should not kiss others nor talk directly into people's faces, and articles which they have used should be dipped in very hot water. A further precaution is to smear open lesions with a mercurial ointment. With modern methods of treatment the secretions cease to be infectious within 24 hours.

CURATIVE.—The remedies most commonly employed for the treatment of syphilis have been preparations of (1) arsenic, (2) bismuth, (3) mercury, (4) penicillin and (5) iodine. The first four destroy the parasites; the last promotes the removal of granulomatous tissue. The position of the most recent remedy, penicillin, is still a matter of some discussion. Most workers are now convinced that it alone is sufficient for the successful treatment of almost every case of syphilis, but others, though admitting the powerful anti-spirochetal properties of penicillin, prefer to supplement it with other remedies. The different remedies will be described separately before discussion of their use in the management of syphilis.

(1) ARSENICAL PREPARATIONS

In consideration of the fact that most workers in this field no longer employ these drugs reference to their use in the treatment of syphilis will be made in the past tense.

They are organic compounds in which arsenic is trivalent or pentavalent. The trivalent preparations were the most frequently used for most forms of syphilis; the pentavalent preparations were used chiefly for syphilis of the central nervous system and for syphilis in infants.

(a) TRIVALENT ARSENICAL REMEDIES.—The first of these was "606" or the Ehrlich-Hata remedy, which was first introduced in 1910. There have been many of these compounds with different trade names which were apt to be confusing, but all except oxophenarsine have been subject to Regulations under the Therapeutic Substances Act, under which, besides the requirements of certain tests for toxicity and therapeutic potency, each must bear on its label an official name according to its chemical constitution. The following are the principal remedies in this class:

- (i) Arsphenamine, or the dihydrochloride of dioxy-diamino-arsenobenzene, which is the original "606" or salvarsan; it must have an arsenical content of not less than 30 per cent. and not more than 34 per cent.
- (ii) The disodium salt of (i), or sodium salvarsan; it contains about 20 per cent. of arsenic.
- (iii) Neoarsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphoxylic acid, which is the original "914", or neosalvarsan; it is sold under the trade names Evarsan, Neokharsivan, Neosalvarsan, Novarsan, Novarsenobillon and Novostab; it must contain not less than 18 per cent. and not more than 21 per cent. of arsenic.
- (iv) Sulpharsphenamine, or the sodium salt of dioxy-diamino-arsenobenzene-methylene-sulphurous acid; it is sold under the trade names Kharsulphan, Metarsenobillon, Myosalvarsan, Sulfarsenol and Sulphostab, and its arsenical content is the same as that of neoarsphenamine.
- (v) Arsphenamine glucoside or Stabilarsan; the arsenical content of the dose stated on the label equals that of the same dose of neoarsphenamine.
- (vi) Silver arsphenamine.
- (vii) Neosilver arsphenamine.
- (viii) Oxophenarsine.

Each of these preparations except oxophenarsine bears the name "arsphenamine" in its official designation, and these as a group will be referred to as the arsphenamine preparations. All but the diglucoside are in powdered form, sealed, in stated doses, in glass ampoules containing a neutral gas. All the powders are yellow except the silver preparations. All oxidise and become increasingly toxic on exposure to air and must consequently be made up and administered as soon as possible after the ampoule has been opened. Oxidation in an ampoule, through a flaw in the glass, makes the powder become darker and sticky. Arsphenamine diglucoside is in solution and ready for use when drawn from the ampoule. It must be used before the expiry date stated on the label.

Arsphenamine (606) is therapeutically the most active of the arsphenamine preparations, but was little used outside the United States of America because of the complexity of its preparation for administration and of its greater tendency to cause serious reactions on the day of injection.

Neoarsphenamine was much the most commonly used of all the arsphenamine preparations. In equivalent dosage it is less active than arsphenamine, but is more easily prepared for administration and causes less general reaction. It causes too much pain to be given by the subcutaneous or intramuscular route, and was, therefore, given intravenously.

Sulpharsphenamine was given by the intramuscular or deep subcutaneous route. It causes comparatively little discomfort when administered in this way. Being relatively stable, its action is inferior to that of neoarsphenamine when it is given intravenously, and even when administered subcutaneously its effect is barely equal to that of intravenous neoarsphenamine. It is more prone than the other arsphenamine preparations to cause blood dyscrasias.

Arsphenamine diglucoside is a convenient preparation in that it is ready for use when drawn from the ampoule, but its immediate effect in causing disappearance of

T. pallidum from the secretions of early lesions is not so great as that of neoarsphenamine in equivalent dosage. Silver arsphenamine and neosilver arsphenamine are emery-coloured powders. They are more active but also more toxic than the other arsphenamines and were therefore given in approximately half the standard dosage of the latter. They were sometimes useful as a change from neoarsphenamine.

Oxophenarsine is a comparative newcomer in this field, although it was originally tested by Ehrlich, it is commonly known as arsenoxide. It is believed to be chemically identical with the spirocheticidal substance which is formed from the arsphenamine preparations in the body. It is m-amino-p-hydroxyphenyl-arsine oxide, and is sold in this country as the hydrochloride, Mapharside (in the U.S.A. as Mapharsen) and the tartrate, Neohalarsine. It is a stable compound which, during the years before penicillin was available, acquired great popularity, especially in the United States of America, and was the arsenical compound of choice for the intensive treatment of syphilis. Its relative efficacy is a matter of some dispute. It has the advantages that it is stable and rapidly excreted and it has been claimed to be less toxic and more efficient than neoarsphenamine. It was useful for intensive forms of treatment in which 3 or more injections of an arsenical were given weekly.

Dosage of arsphenamine compounds—Doses of the different preparations described varied greatly with circumstances. Some details of dosage will be given in discussing schemes of treatment (see p. 222). In a case of primary or secondary syphilis it was reasonable to aim to bring about rapid disappearance of *T. pallidum* from the secretions of external lesions, and in the case of an adult when there was no contra-indication it was the usual practice to start with 0.45 g. neoarsphenamine.

Technique of administration of arsphenamine preparations—Intravenous route—In the case of neoarsphenamine the dose was dissolved in 10 ml. of distilled water. The solution was drawn into a syringe, which was then fitted with a fairly fine needle (S.W.G. 22). The technique was that of any intravenous injection. The median basilic or other convenient vein was distended by fixing an elastic band round the upper arm and asking the patient to grasp a roller bandage. The operator looked along the vein and steadied it with the index finger of his spare hand laid on the skin below the site. The eye of the needle was made to look away from the skin and the shaft of the needle held almost parallel to it. The point of the needle was inserted into the vein and a pull on the piston caused blood to flow back into the syringe indicating that the needle was properly within the vein. The rubber band was then released and the piston slowly pressed home. After the syringe had been emptied a little blood was aspirated into it to clear the needle of any solution.

Deep subcutaneous and intramuscular routes—Arsphenamine remedies are believed to have a greater therapeutic effect when administered subcutaneously or intramuscularly, but most of them cause too much pain when given in this way, almost the only one which could be employed for the purpose was sulpharsphenamine. The dose was dissolved in distilled water, or in a glucose solvent containing an analgesic prepared for the purpose. In either case as little as 1 ml. might be used, but 2 ml. of the glucose solvent seemed to be more effective in preventing local reaction. The technique of intramuscular injection is described on p. 217. Deep subcutaneous injection of sulpharsphenamine caused less pain than intramuscular injection and was usually preferable. It was given as follows. In the upper and outer quadrant of the gluteal region the skin and fat were pulled away from the underlying fascia by grasping them with the thumb and fingers of the left hand and a needle (S.W.G. 20) $1\frac{1}{2}$ inches in length was inserted obliquely at the base of the pyramid thus produced. The needle was made to under-run the fat so that its point might scrape on the fascia overlying the gluteal muscles. The charged syringe was fitted to the needle and the injection given fairly slowly. The site was then massaged with a pad of lint.

The toxic effects of arsphenamine preparations are described on page 229.

Certain other reactions may follow the administration of arsenicals but these are not due to the toxicity of these preparations. The commonest of these is the *Jarisch-Herxheimer reaction* which is a focal and general reaction which may follow the use of a rapidly effective drug, such as an arsenical or penicillin, at the commencement of treatment. It occurs in about 50 per cent. of cases of primary and secondary syphilis in which the first injection may be followed within a few hours by fever, headache, malaise, pain in the joints and limbs and exacerbation of the symptoms and signs of infection. At this stage it is not harmful but the patient should be warned of the possibility that it may occur. Ordinarily the reaction occurs within 12 hours and lasts for not more than 24 hours. The cause is unknown and there is little evidence to support the theory that it results from liberation of toxins following the destruction of large numbers of spirochaetes. In the late stages of syphilis the reaction is less common and usually slight. In most cases there is no more than slight fever of which the patient may be unaware. Occasionally, however, serious results have followed through exacerbation of severe involvement of the central nervous system, complete blockage of a large cerebral vessel or of the opening of a coronary artery, perforation of the aortic wall or of an aneurysm, or oedema of the glottis in cases of gummatous infiltration of the larynx. Such cases are very rare but, even so, they can and should be prevented by care in the institution of treatment in cases of late syphilis, in which nothing is to be gained by speed and intensity of treatment. Further reference will be made to this reaction in describing the effects of treatment with penicillin.

Neuro-recurrences are also not direct toxic effects of treatment with arsphenamines. Lesions of various cranial nerves, especially the seventh and eighth, became more common shortly after the introduction of the organic arsenical remedies and were later shown to be syphilitic recurrences due to the small amount of treatment given in the early days of "606". They became very rare when bismuth or mercury was given in conjunction with the arsenical remedies.

Contraindications to the use of arsphenamine preparations.—The use of arsenicals was absolutely contraindicated in cases of severe systemic disease such as chronic nephritis, Addison's disease, severe disease of the liver and hæmophilia, and also in the cases of patients who had shown intolerance to the drugs in the past. In view of the fact that an efficient non-toxic substitute is now available these drugs are certainly better avoided in cases of diabetes mellitus, alcoholism and of chronic diseases of the skin such as eczema or seborrhoea. Older patients showed poor toleration to arsenicals and it was customary not to use them for patients over the age of 55 years.

Precautions to be observed in the use of arsphenamine preparations.—It is essential to observe scrupulous care in the technique of injection, especially in the sterilisation of syringes and needles, and careful watch must be kept for the appearance of signs of intolerance during treatment. Patients who receive intravenous injections should fast for 2 hours beforehand. The indications for the use of arsenicals are now so few that these problems seldom arise. Nevertheless, because of the increasing number of patients who are becoming sensitised to penicillin it is still important that the method of use and the contraindications of the arsphenamines should be understood.

Administration of oxophenarsine compounds.—These compounds were always given intravenously dissolved in 8 to 10 ml. of distilled water, as with nearsphenamine. Unlike nearsphenamine, oxophenarsine may be brought into solution by shaking, and the solution may be left standing, without danger of increasing toxicity. The injection was given quickly in order to avoid pain along the vein or venous thrombosis. The standard dose for an adult is 0.04 to 0.06 g., and for the routine prolonged treatment of syphilis it seemed advisable to give this dose twice weekly instead of once, which was the usual practice with standard doses of nearsphenamine.

(b) **PENTAVALENT ARSENICAL REMEDIES.**—The principal remedies of this class which have been used in the treatment of syphilis are: (i) Sodium N-pbenylglycine-amide-p-arsenate (tryparsamide); (ii) 3-acetyl-amino-4-hydroxyphenylarsonic acid,

or acctarsol (Kharophen, Orarsan, Spirocid and Stovarsol); (iii) the sodium salt of (u); and (iv) the diethylamine compound of (ii), Acetylarsan.

Tryparsamide was the most important of these because of its value in the treatment of syphilis of the central nervous system. It is a white powder easily soluble in water, and the dose for an adult is from 2 to 4 g. (usually 3 g.) freshly dissolved in distilled water and injected intravenously once a week. A course lasted 10 to 12 weeks, and the interval between any two courses was a month or 6 weeks.

Acctarsol was introduced in 1922 primarily as a drug to be given by mouth for the prophylaxis of syphilis. Subsequently it was used extensively for the treatment of infants with congenital syphilis. Acctarsol-sodium and Acetylarsan were given by injection; their effects were like those of acctarsol.

(2) MERCURIAL PREPARATIONS

Mercury was formerly the main remedy for the treatment of syphilis, but it has been almost entirely superseded by bismuth. It is now used occasionally in cases where injections are impracticable. Mercury and bismuth had the advantage that small amounts of them could be kept in the circulating blood almost continuously, so that anti-spirochætal action was maintained after the arsphenamine had been excreted until it was safe to administer another arsenical injection. This method of treatment was based on the view which still prevails, that it is necessary for an anti-syphilitic remedy to be present constantly in the body fluids for a considerable period to ensure destruction of all the spirochætes of syphilis.

Methods of administration.—The oral method was much favoured, but was apt to cause gastro-intestinal disturbance; like other oral remedies for syphilis it had the disadvantage that regularity of treatment depended upon the memory and co-operation of the patient. Mercury by mouth is still occasionally useful when a patient cannot take injections or continue injections or remain under close observation. The following preparations have proved useful: (1) hydrargyrum cum creta, gr. 1 to 2; (2) hydrargyri iodidum viride or flavum, gr. $\frac{1}{2}$ to $\frac{1}{4}$; (3) hydrargyri perchloridum, gr. $\frac{1}{4}$; (4) hydrargyri tannas, gr. 1 to 3; (5) pil. hydrargyri, gr. 1 to 3; (6) liq. hydrargyri perchloridi, min. 30 to 60. The latter is often prescribed in a mixture with potassium iodide. The first five of these were usually given in the form of pills, often combined with a little opium, e.g. pulv. ipecacuanhæ et opii gr. 1 to 2, or extractum opii gr. $\frac{1}{4}$ to counteract the irritant effect of the metal upon the gastro-intestinal tract; but it is better to prescribe the sedative separately, and to regulate the dosage as required. It was customary to give courses of 6 weeks' duration, gradually increasing the daily intake of mercury until slight signs of stomatitis appeared, and then to reduce the dose. An adult patient could usually take from $\frac{3}{4}$ to $1\frac{1}{2}$ grains of the yellow or the green iodide given daily in this way. Rest periods between courses varied from 1 to 4 weeks.

Unction was a useful method of administering mercury. It had to be done by a skilled rubber, and had the inconvenience of soiling the skin and clothes. Five to 10 g. of mercurial ointment, unguentum hydrargyri B.P., containing 30 per cent. of mercury, were rubbed for 20 minutes into the skin of thighs, calves, arms, chest and back on successive days, avoiding hairy areas because of the danger of folliculitis. A bath was taken on the sixth day and the cycle restarted on the seventh. The number of rubbings in one course varied from 60 to 200; the length of a course depended on the patient's tolerance, which was judged by the state of the gums, the maintenance of weight and general well-being.

Intramuscular injections of mercury are no longer used because bismuth administered in this way is more effective, less toxic and less painful. Details of intramuscular preparations of mercury are therefore omitted.

The toxic effects of mercury are considered on page 233.

(3) PREPARATIONS OF BISMUTH

Bismuth was applied to the treatment of syphilis by Sazercac and Levaditi in 1921, and has supplanted mercury in all cases for which intramuscular or deep subcutaneous injections of heavy metal are indicated. Because bismuth is more effective and better tolerated than mercury the almost universal practice before the introduction of penicillin was to use bismuth in conjunction with arsphenamine preparations for the treatment of syphilis in all stages, except general paralysis.

Bismuth is administered almost exclusively by the intramuscular route, and many different preparations are available. They may be classified according to their solubility as follows: (a) solutions in water; (b) solutions in oil; (c) suspensions of bismuth metal or insoluble salts of bismuth in watery or oily media. Absorption and excretion are most rapid with the watery solutions and least so with the insoluble suspensions.

Watery solutions are now seldom used because, on account of rapid absorption and excretion, they are very apt to produce toxic effects. *Oily solutions* contain organic lipo-soluble compounds dissolved in oil. In absorbability they are intermediate between watery solutions on the one hand and insoluble suspensions on the other. The following preparations of this kind have been used in this country. They are described by their proprietary names without details of their chemical formulæ which are rather complex. The bismuth content per millilitre is stated in brackets after each preparation: Bivatol (0.035 g.); Cardyl and Neocardyl (0.05 g.); Neo-olesal (0.03 g.) and Stabismol (0.1 g.). If these preparations are used it is advisable to give two doses each week at intervals of 3 to 4 days, because of the relative rapidity of absorption and excretion. *Insoluble suspensions* of bismuth have been those most commonly used for antisyphilitic treatment. Only three of these are included in the British Pharmacopœia, namely: (1) *injectio bismuthi*, B.P., which is precipitated bismuth in a dextrose solution with cresol containing 0.2 g. of bismuth per ml. (2) *injectio bismuthi oxychloridi*, B.P., which is a watery suspension of bismuth oxychloride containing 0.13 g. of bismuth per ml. (3) *injectio bismuthi salicylatis*, B.P., which is a 10 per cent. suspension of bismuth salicylate in olive oil with camphor and phenol containing about 0.6 g. of bismuth per ml.

Technique of injection.—The technique of intramuscular injection is simple. By far the best site is the upper and outer quadrant of the gluteal region; the upper third of the vastus lateralis muscle and the deltoid muscle are much less satisfactory. A needle of S.W.G. 20, 1½ inches long, is introduced almost to its full length, perpendicularly to the skin surface. The base is examined to see that no blood is oozing from it, the syringe is applied, the piston partially withdrawn to make sure that the point of the needle is not within a vein, and the piston is then pressed home. The needle is withdrawn and the site is well massaged with a ball of cotton wool. Before an insoluble preparation is drawn into the syringe, the suspension should be well mixed, either by stirring with a glass rod or by energetic shaking of the bottle.

Toxic effects of bismuth.—The toxic effects are few. Care must be taken to avoid injecting preparations of bismuth into veins because they are then highly toxic and, if an insoluble preparation is used, pulmonary embolism may result.

Stomatitis.—A slaty-blue line commonly appears at the margin of the gums of patients receiving this treatment, especially adjoining the molar teeth. It is due to the formation and deposition of bismuth sulphide and is only found in association with infection of the gums and pocketing. The appearance of the blue line is not in itself a bar to the continuation of treatment, but if the gums become swollen, tender and spongy and bleed easily the treatment must be stopped. In some cases in which oral hygiene has been neglected, ulcerative stomatitis may supervene. Treatment is preventive by preliminary dental care. The treatment of established stomatitis is by the cleansing of gums and pockets with antiseptics such as potassium

ehlorate and hydrogen peroxide or by the use of mouthwash containing these preparations. Good results have been obtained with dimercaprol (B.A.L.) in the dosage recommended for the treatment of arsenical poisoning (see page 231). The blue line is likely to persist for many months after the administration of bismuth has ceased. *Nephritis*.—Albuminuria is found occasionally, especially with the soluble preparations. It is an indication to stop bismuth, for otherwise the patient may develop acute nephritis. The urine should be tested before each injection. *Intestinal disturbance*, in the form of colicky pains with, perhaps, constipation or diarrhoea, is uncommon. Rarely patients receiving this treatment complain of *restlessness, insomnia, rheumatic pains and general depression*; the possible relationship of such symptoms to the administration of the drug should be remembered. Various *eruptions of the skin* have been described as due to the administration of bismuth, including exfoliative dermatitis and purpura, but these complications must be very rare.

Choice of preparations of bismuth.—In the treatment of syphilis the main value of preparations of bismuth has been to supplement the action of the arsenical drugs which, because of rapid excretion, produced transitory effects unless given with such frequency as greatly to increase the incidence of toxic complications. For the purpose of slow absorption and prolonged effect the insoluble preparations have been the most satisfactory, and in this respect there has been little to choose between the three preparations recognised by the British Pharmacopœia. The writer has a preference for injectio bismuthi, B.P., which, in addition to being effective, rarely causes local pain or tenderness. The oily solutions of bismuth have been recommended for use in cases where more quickly acting remedies are required, but it is difficult to see how these preparations could match penicillin or the arsenicals in this respect. On the other hand the oily solutions were of value in the treatment of those patients who were or became intolerant of the arsenicals in the years before penicillin was introduced.

(4) PENICILLIN

The general properties and the methods of administration of penicillin are described elsewhere in this book. Here it is necessary only to describe: (a) the effect of the drug on the different manifestations of syphilis; (b) the methods of using it for the treatment of syphilis which seem most effective in the light of knowledge available at the time of writing and (c) the toxic effects which may be encountered in the course of this treatment.

Of the various types of penicillin which have been isolated benzyl penicillin, (penicillin II or G), appears to be the most effective for the treatment of syphilis. Investigative work in the United States indicated that pure crystalline benzyl penicillin gave results which were moderately superior to those obtained with commercial penicillin. Commercial penicillin as originally distributed in this country was claimed to contain at least 85 per cent. of benzyl penicillin and therefore to be an effective drug for this purpose.

Penicillin, in appropriate doses, has an effect upon *T. pallidum* which is at least equal to that of the best arsenical compounds, and, correspondingly, its effect in producing healing of the various manifestations susceptible to the action of the arsenical compounds is at least equally satisfactory. Penicillin has, of course, the great advantage over the arsenical compounds that for most patients it is practically non-toxic, and it is possible to give large doses very frequently with impunity. A very important therapeutic advantage over the arsenical compounds is that it reaches the *fetus in utero* far more easily. It is very effective indeed in preventing fetal infection, or in curing the fetus if it is already infected. For the treatment of neurosyphilis, also, the effect of penicillin appears to be superior to older methods of treatment even though the drug appears in the cerebrospinal fluid either in very small quantity or not at all after intramuscular administration of ordinary dosage.

Whether penicillin should be used alone or in conjunction with other antisymphilitic remedies will be discussed in the appropriate section.

Administration and Dosage.—Continuous administration of penicillin was found to be impracticable for the treatment of syphilis, because of the necessity of confining the patient to bed and the frequency of thrombophlebitis with intravenous drip and painful local reactions with continuous intramuscular or subcutaneous administration. The method of choice was found to be that of intermittent intramuscular injections. At first, the drug was dissolved in sterile distilled water or isotonic sodium chloride solution, in concentration of 50,000 to 100,000 units per ml., and was injected deep into the upper and outer quadrants of the buttocks every 2 or 3 hours, day and night, in doses of 20,000 to 100,000 units. Some give the injections into the outer thigh muscles or the deltoids, but general experience indicates that injections into the buttocks cause far less discomfort to the patients. Subcutaneous injections are less satisfactory because they need to be given in more dilute solution and may cause painful local reactions.

Penicillin has been given intrathecally but the earlier impure preparations were apt to cause dangerous toxic reactions. In view of the evidence that good results are obtained by intramuscular administration in cases of neurosyphilis, the intrathecal route is better avoided.

Penicillin by mouth is said to require dosage five times as large as that used intramuscularly. For outpatients suffering from syphilis this method of treatment is inadvisable because of the difficulty of ensuring that the prescribed doses are taken. There is, also, considerable individual variation of absorption of the drug from the gastro-intestinal tract. For these reasons penicillin by mouth is not recommended for the treatment of syphilis.

Various preparations have been devised to delay the absorption of penicillin when given by intramuscular injection, by suspending it in media which repel moisture. The first effective preparation of this kind was a suspension of calcium penicillin in arachis oil thickened with 4.8 per cent. of beeswax. A more satisfactory preparation is procaine penicillin which is a chemical compound between procaine and penicillin and may be administered in oily or watery suspension. It is painless, non-toxic and effective. Effective blood levels of penicillin can be maintained for as long as 24 hours by an average single dose of 600,000 units of procaine penicillin contained, in the case of the oily suspension, in 2 ml. of oil. This method is therefore applicable to the treatment of outpatients. A further development is the addition of the water-repellent aluminium monostearate in 2 per cent. concentration to oily suspension of procaine penicillin of fine particle size. This still further prolongs absorption so that the effect of an average dose may extend over several days. A preparation now under trial is benethamine-penicillin (N N'-dibenzylethylenediamine dibenzyl-penicillin). It has been shown that after single injections of 2.5 mega units of this preparation therapeutically effective levels of penicillin can be found in the blood stream for 2 weeks or even more. It is hoped that by this means the treatment of syphilis with penicillin may be restricted to one or two injections.

Toxic effects of penicillin.—Penicillin is relatively non-toxic except when given intrathecally. Serious reactions have been rare although in recent years some deaths have been reported from anaphylactic shock of patients who have become sensitised in the course of earlier administration of the drug. Precautions which should be taken to avoid this dangerous reaction are described on pp.10, 220. Local, systemic and cutaneous reactions were common with earlier impure preparations but they have become much less so with the pure preparations now available. The more serious reactions reported include thrombophlebitis after intravenous injection or intravenous drip, and generalised exfoliative dermatitis resulting from sensitisation. Other effects are fever of varying degree, reactions like serum sickness with fever, scarlatiniform or morbilliform rash and arthralgia or serous effusions into joints,

local vesicular eruptions, urticarial and other rashes, including generalised erythematous macular and maculo-papular eruptions, resembling erythema multiforme in some cases. Patients with a pre-existing fungus infection have sometimes experienced exacerbation of that infection following injections of penicillin.

With the exception of urticaria most of these reactions have been uncommon. Some seem to have been due to impurities in the drug but some are certainly due to penicillin itself. Severe reactions immediately following upon injections of procaine penicillin in watery suspension have been described. The patients were excited and noisy, and in one case, violent; they complained of a feeling of impending death. The reaction was attributed to accidental intravenous injection of the preparation. In cases of reactions attributed to sensitisation the administration of anti-histamine drugs has given relief from symptoms in some instances.

Jarisch-Herxheimer reaction.—This reaction has been considered in relation to treatment with the arsenicals (see page 215). With penicillin the effects are very similar, but certain aspects of them require special consideration. The reaction is not uncommon in cases of neurosyphilis treated with penicillin. Ordinarily, the results are not serious, but severe effects have been reported, including exacerbations of psychoses, convulsions, transverse myelitis, mania, hallucinations, exacerbations of lightning pains, parietic deterioration progressing to death and optic atrophy progressing to blindness. It has been suggested that patients with late syphilis should commence treatment with very small doses of penicillin with gradual increase of dosage, but experimental work has shown this to be an ineffective precaution, indicating that the reaction is of the all or none type. It does not occur with minute doses but does occur when the trigger dose is reached and then with full force, irrespective of the size of the dose. In most cases the reaction can be prevented by a preliminary course of injections of bismuth, which, of course, acts much more slowly and seldom produces this effect. Bismuth, however, will not protect from the Jarisch-Herxheimer reaction

(b) The dosage of penicillin for gonorrhœa should be the minimum consistent with the probability of a good result. Details will be found on page 65

(c) Penicillin should not be used for the treatment of patients with gonorrhœa who also have lesions suggestive of syphilis until those lesions have been fully investigated

(d) All patients treated with penicillin for gonorrhœa should remain under observation with monthly serological tests for at least 3 months, and a final serological test should be performed at the end of 6 months

(e) A sharp febrile reaction within the first 24 hours after the use of penicillin for gonorrhœa suggests the possibility of concurrent early syphilitic infection. It has been shown that the Jarisch-Herxheimer reaction may occur in the incubation period of syphilis

(5) IODINE PREPARATIONS

Iodides promote the absorption of syphilitic granulation tissue and may be useful in the later stages of infection. Potassium iodide is most often given by mouth in doses of gr 5 to 30 three daily. It is usually prescribed with alkali to avoid gastro-intestinal disturbances. Most patients tolerate gr 5 to 10 three times a day without difficulty, but iodism may result from higher dosage. The common manifestations are due to increased flow of secretions, causing coryza, salivation and lacrimation. There may be pain over the accessory nasal sinuses. Sometimes the drug produces an acneiform eruption. The benefit to be derived from this remedy is not now sufficient to justify perseverance with it in the face of major discomfort. Sodium iodide is probably the best preparation for intravenous injection. After testing the patient's tolerance by giving some potassium iodide by mouth, a dose of gr 150 of sodium iodide dissolved in 100 ml or more of sterile distilled water may be given intravenously every 24 to 48 hours up to a total of 20 to 30 injections in a course.

The Treatment of Acquired Syphilis.—The main principles to be observed in the treatment of syphilis are as follows: (1) treatment should begin as soon as possible. The earlier treatment is begun the better the results, (2) the amount and duration of treatment should be sufficient to ensure the probability of cure but over-treatment should be avoided, (3) due attention should be given to the general health of the patient, (4) observation and testing after treatment should be careful and prolonged. There are some failures following even the best methods of treatment and long observation may be necessary before these can be recognised.

EARLY SYPHILIS

There has been some division of opinion on the question as to whether penicillin alone is sufficient for the treatment of cases of early syphilis or penicillin should be supplemented by a full course of treatment with an arsenical and bismuth or with bismuth alone. Those who have advocated the use of penicillin alone have based their argument on the high proportion of successes obtained and the absence of toxic effects following this treatment. Those who have taken the contrary view have argued that the reported incidence of relapse following penicillin alone, which has been as high as 15 per cent in some series, is considerable and that in any case experience with penicillin has been insufficient to justify absolute reliance upon it.

In this country clinicians were first inclined to support the more conservative attitude, but with increasing experience it has become evident that the addition of arsenicals and bismuth to penicillin does not increase the proportion of successes in the treatment of early syphilis but does add to the incidence of major and minor toxic effects. With the decline in the incidence of early syphilis in the population of this

country and of the United States the failures of treatment with penicillin alone have become considerably fewer, and it seems reasonably clear that a number of so-called infectious relapses were in fact reinfections; the two conditions often cannot be distinguished with certainty. Thus penicillin alone is the treatment of choice. Experimental work in the United States has indicated that if crystalline benzyl penicillin is used in watery solution in the treatment of early syphilis the optimum dose is about 5 million units and the optimum duration of treatment about 7 to 8 days. Injections should be given day and night at intervals of 2 to 3 hours. An effective method of treatment is to give 100 injections each of 50,000 units intramuscularly, every 2 hours day and night. For such treatment it is necessary to admit patients to hospital.

To avoid admission to hospital and to reduce the number of injections procaine penicillin may be used in oily or watery suspension or, better still, in oily suspension containing 2 per cent. aluminium monostearate. A satisfactory method is to give 10 consecutive daily intramuscular injections each of 600,000 units, totalling 6 million units.

Success from this treatment may be anticipated in 95 per cent. or more of the cases.

Those who advocate the addition of a full course of arsenicals and bismuth to standard dosage of penicillin recommend additional treatment of the following kind:

1st Week	Neoarsphenamine 0.45 g. intravenously.
			Bismuth metal 0.3 g. intramuscularly.
2nd to 10th Week	Neoarsphenamine 0.6 g. intravenously.
			Bismuth metal 0.3 g. intramuscularly.

Oxophenarsine may be substituted for neoarsphenamine in dosage of 0.06 g. twice weekly.

The practice of using arsenicals is steadily diminishing in favour. The results of our own experience indicate that they now have no place in the routine treatment of syphilis.

Observation after treatment.—Following treatment with penicillin the patient should remain under close observation with monthly clinical examinations and tests of the blood for the first 6 months, and thereafter examination and blood tests every 3 months for at least 2 years. During the period of observation the cerebrospinal fluid should be tested. This is often done at the end of 6 months after the completion of treatment and again, finally, 2 years after treatment. It is, however, very uncommon to find changes in the cerebrospinal fluid after treatment with penicillin which proves effective in other respects, and a point against early lumbar puncture is the fact that the procedure can produce a severe reaction which may make the patient quite determined not to repeat the experience. If, therefore, the cerebrospinal fluid is examined and found to be normal at some time during the second year of observation after treatment, it need not be tested again. If, however, the blood tests remain positive beyond the expected period, or if a relapse occurs, it is always advisable to test the fluid earlier.

After 2½ years of observation cure may be presumed, but it is customary and advisable for the patient to be examined and to have blood tests once a year for some years after this period.

Failures of treatment.—The critical period for the development of clinical or serological relapse is between the fourth and ninth months after treatment, although relapses, or possibly reinfections, have been observed as early as 4 weeks and as late as 3 years.

The indications for further treatment are three in number:

(1) **Clinical relapse.**—When the relapse is of the muco-cutaneous or infectious type it may be difficult or impossible to be sure that the patient has not been reinfected. Cases of true relapse are often resistant to treatment and on re-treatment it is advisable

to double the original dosage of penicillin and to consider the possibility of giving, in addition, one full course of neosarsphenamine and bismuth. The birth of a syphilitic child to a treated syphilitic mother is a form of clinical relapse.

(2) *Serological relapse*.—This is said to occur when tests originally negative, as with sero-negative primary syphilis, become positive; or tests originally positive become negative and then positive again; or tests originally positive show at first no change or decline in the quantitative titre, but subsequently show progressive rise in titre; or when tests of the cerebrospinal fluid, originally negative, become positive. Serological relapse commonly precedes clinical relapse.

(3) *Serological resistance*.—The decision as to the period of time after which persistence of positive serological tests is regarded as evidence of failure of treatment of early syphilis is an arbitrary one. In much of the experimental work on the subject the period was fixed at 1 year after treatment. For the routine management of cases, failure may be presumed if the quantitative tests show no fall in titre after 4 to 6 months of observation.

LATE SYPHILIS

After the third or fourth year of infection the details of treatment depend very much on the presence or absence of involvement of viscera and of the nervous system, the treatment of which is discussed elsewhere in this work. In these later cases it is very important not only to examine carefully the cardiovascular and nervous systems, but also to test the cerebrospinal fluid as part of the routine investigation. If tests of the fluid are negative they are unlikely to become positive later, and the central nervous system is unlikely to be affected.

LATENT SYPHILIS.—In these cases the only evidence of the disease is the positive serological tests. In the past it was shown that such patients who received full dosage with arsenicals and bismuth remained in good health after prolonged observation in more than 95 per cent. of the cases, whether or not the serological tests became negative. Penicillin is no more effective than arsenic and bismuth in reversing positive serological tests to negative in these cases. Full assessment of the value of penicillin in these cases will take many years. Its use for the treatment of latent syphilis is based on the assumption that, being of value for early syphilis, it must be effective in other cases, which seems a reasonable assumption. Penicillin has the advantage of brevity and safety and it is common practice to use it for latent syphilis in similar dosage to that recommended for the earlier stages of the disease. Many patients with latent syphilis report improvement in general health after this treatment.

BENIGN LATE SYPHILIS.—The evidence is that prompt healing of cutaneous, mucosal and osseous gummata, and of other benign late lesions, follows the administration of 2.4 to 4.8 million units of penicillin. Common practice is to use rather more penicillin such as from 6 to 8.4 million units spread over 10 to 14 days. As for early syphilis, it is good practice to give a daily injection of 600,000 units of a reliable preparation of procaine penicillin. The immediate results are as good as those obtained with arsenicals and bismuth, and there is no reason to suppose that the ultimate results will be inferior.

The fact that serological tests remain strongly positive after this treatment in many of the cases is not an indication for further treatment. On the other hand, prolonged observation is important and re-treatment should be undertaken for any evidence of clinical relapse or consistent rise in titre of the quantitative serological tests.

Whether it is justifiable to use penicillin in the treatment of these cases of late syphilis without preliminary treatment with injections of bismuth and perhaps iodide by mouth is an open question. The tendency in the United States is to discount the importance of the Jarisch-Herxheimer reaction in cases of late syphilis except in certain cases of neurosyphilis. There is no doubt that serious effects of this reaction

are rare and they present no problem in the majority of cases. There remains the possibility of some serious effect in an occasional case. It is obviously impossible to exclude by clinical examination the contingency of asymptomatic involvement of vital organs, and nothing is to be gained by speed and intensity of treatment in cases of long standing. On general principles, it is well to give preliminary treatment with weekly intramuscular doses of gr 0.3 of injectio bismuthi for 4 to 6 weeks, combining the treatment with gr 5 or 10 of potassium iodide by mouth three times a day.

ASYMPTOMATIC NEUROSYPHILIS

In cases of latent syphilis in which positive changes in tests of the cerebrospinal fluid indicate involvement of the central nervous system, it is customary to give a rather longer course of injections of penicillin. Common practice is to give a daily injection of 600 000 units of procaine penicillin for 21 days, totalling 12,600,000 units. In these cases the guide to the efficacy of treatment is the cell count and the protein content of the cerebrospinal fluid. Earliest and most striking is the reduction of the cell count which, in successful cases, returns to normal by 10 to 24 weeks after treatment and remains normal. The protein content also responds, but rather less promptly. Normal values are usually reached by the sixth month and maintained thereafter. The Wassermann reaction and colloidal tests improve more slowly and may show positive changes for an indefinite period. The response of these tests is more prompt and satisfactory with early than late asymptomatic neurosyphilis. The usual practice is to give no additional treatment if the patient remains well and the cell count and protein level in the cerebrospinal fluid remain within normal limits. Tests of the cerebrospinal fluid should be repeated at intervals of 3 months for the first year after treatment and thereafter yearly for some years.

If further treatment is required a second course of penicillin or, if necessary, several courses of penicillin should be given. It is doubtful whether the use of the pentavalent arsenical, tryparsamide, in the treatment of neurosyphilis is now justified. If it is to be used it is essential first to ensure that there is no ophthalmoscopic evidence of optic atrophy and that there is no contraction of the visual fields, for the dangerous complication is toxic amblyopia. For an adult the usual practice is to commence with an intravenous injection of 2 g of tryparsamide dissolved in 5 to 10 ml of sterile distilled water. Thereafter weekly injections each of 3 g of the drug are given for another 9 weeks, which completes the course. Occasionally, during the first course, a patient may complain of subjective visual disturbance such as "shimmering" or mistiness on looking in some particular direction. In such a case the injections must be discontinued and should not be resumed. The visual fields should be charted by perimetry at intervals of 2 weeks during treatment. Several courses of this treatment may be given with intervals of 1 month between the courses. For genuine failures of treatment with penicillin pyretotherapy is the best form of supplementary treatment. This may be given by inoculation with the parasite of benign tertian malaria, allowing 10 or more paroxysms of fever before suppression with antimalarial therapy. Alternatively, fever may be given by physical means, as with the heat-labile hypertherm or by repeated intravenous injections of vaccine such as typhoid paratyphoid vaccine (TAB). Pyretotherapy is a highly technical procedure and should not be undertaken without full knowledge of the technique and of possible complications and how they may be avoided or treated.

which is seldom taken and most clinicians are satisfied with lesser standards. If treatment appears to have been successful the risk is probably very slight after a year of observation and, provided that the partner in marriage is made aware of the slight risk, permission to marry or to resume married life may be given at this time.

CONGENITAL SYPHILIS

An infected mother can transmit syphilis to her offspring long after she has ceased to be sexually contagious. In general the more recent the infection in the mother the more severe the effects of transmitted infection on the *fœtus*. The theoretical course of the obstetric history of a syphilitic woman is stated in *Kassowitz's Law*, according to which early pregnancies result in miscarriages progressively later in pregnancy, followed by the delivery of stillborn or macerated *fœtuses* at term, then by living syphilitic infants and finally by healthy infants. This kind of history, which is presumed to be due to gradual attenuation of infection, is seldom obtained. In practice, miscarriages may alternate with stillborn or living syphilitic children and a healthy infant may be born between two who are infected. It has even occurred that only one of twins was syphilitic. It is now generally agreed that infection always occurs from the mother by way of the placenta and that infection is not transmitted in the first 3 months of life. It may be assumed that miscarriage in the first 3 months of pregnancy is not due to syphilis. In the past it has been stated that the syphilitic placenta can be recognised by macroscopic appearances and, with more certainty, by microscopic changes in the chorionic villi. This view is now discredited and it seems clear that examination of the placenta does not help in this diagnosis unless *T. pallidum* can be found, which is seldom possible.

Symptoms and Signs.—The clinical manifestations of congenital syphilis may be divided into three groups, those which appear early, those which appear late and the stigmata. The early lesions are for the most part infectious and resemble those of secondary syphilis in the adult; the late lesions include gummatous lesions indistinguishable from those of tertiary syphilis; and the stigmata are scars or deformities resulting from early or late lesions.

(1) **EARLY.**—*The Skin and Mucous Membranes.*—The syphilitic infant born alive may show an eruption of large, rounded, dusky-red papules surmounted by bullæ containing serum or pus, the so-called, *bullous eruption* or *syphilitic pemphigus*. The fluid contains *T. pallidum* in large numbers. Some 3 to 4 weeks after birth, or perhaps considerably later, various rashes may appear which are identical in appearance with those found in secondary syphilis. The papular eruption is the commonest. All these eruptions tend to be widespread, involving the whole of the trunk and the limbs, but they may be particularly well-marked in the napkin area, on the skin round the nose and mouth and on the palms and soles. Annular lesions are particularly common and there may be extensive crusting. In moist areas, and where the rash is exposed to friction, the affected areas may become reddened and glazed. Condylomata lata may be found especially in the ano-genital area, and, where the rash is profuse and becomes confluent at the angles of the mouth and nose, ulcerative fissures may form. These sometimes leave radiating linear scars, *rhagades*, which remain as stigmata of the disease. Sometimes the skin is yellowish, or yellowish-brown in colour, the so-called *café-au-lait* tint and if, which is common, there is much wasting, the skin may be wrinkled, giving to the infant's face the appearance which has been called the *old man look*. There may be patchy loss of hair, chiefly at the sides and back of the scalp, *syphilitic alopecia*. Rarely, the syphilitic infant may grow an abundant crop of hair, the so-called *syphilitic wig*. Syphilitic papules may involve the nail beds, causing infiltration and oozing of serum round the nail which may be loosened and shed, *syphilitic onychia*. The new nails may be opaque,

irregular and narrowed at the base. Mucous patches may be found in the nose, mouth, throat and larynx. The nasal lesions may cause discharge from the nose which is persistent and may be bloodstained, nasal obstruction may cause difficulty in feeding. The nasal discharge is infectious and syphilitic moist papules may appear at the margins of the nares. Discharge and obstruction give the typical picture of syphilitic snuffles. As the result of laryngeal infection the infant's cry may be hoarse and raucous. Gross secondary anaemia is common in these severely affected infants.

Lymphadenitis—Rubbery discrete non-tender enlargement of lymphatic glands is common.

Liver and Spleen—As the result of early syphilitic infection the abdomen may be grossly swollen, due to enlargement of liver and spleen. The enlargement of the liver is due to abnormal persistence of fetal blood forming islands and to pericellular fibrosis, resulting from the spirochætal invasion.

The bones—The long bones may be affected in various ways. In the first 6 months of life *osteochondritis* is a very common result of congenital syphilis and may be detected very early by radiographic examination. In severe cases the ends of the bones may be very painful and tender and, because of the pain on movement, the infant may appear to be paralysed, *syphilitic pseudo-paralysis*, or may scream when handled. Swelling of the epiphyseal ends of the bones may be obvious. Pathological fractures, separation of epiphyses and suppurative arthritis are possible sequelæ. Radiologically, epiphyses may be enlarged, the epiphyseal line is broad and irregular, the zone of provisional calcification is sclerotic and shows irregularity like the teeth of a saw, there are irregular patches of osteoporosis in the diaphyses, particularly at the metaphyseal ends, and there is subperiosteal deposition of new bone. In the second 6 months of life the signs of *osteochondritis* disappear, but the evidence of *periostitis* persists and becomes more marked. Successive layers of new bone are laid down on the surface of the cortex under the periosteum in regular fashion. *Dactylitis* may occur in the second year of life. It may cause fusiform swelling of proximal phalanges of one or more fingers, or, more rarely, toes. *Choroiditis* may occur in the early months of life and may be overlooked. *Iritis* is rare.

(2) LATE—Lesions of the tertiary type may appear as early as the third year of life or at any time subsequently. They occur most commonly between the ages of 7 and 14 but may be delayed until adult life. Gummata involving the skin have no features which distinguish them from similar lesions due to acquired syphilis. Gummata of the mouth and throat are particularly common and may result in perforation of the palate or great deformity of the soft palate and pillars of the fauces. The commonest late lesion is *interstitial keratitis*, which may begin at any age from 4 to 30 years, or even later. Usually it starts in one eye, but in spite of treatment the other is likely to be involved after an interval which may vary from a few weeks to many years. The patient complains of photophobia and pain in the affected eye. At first there is seen to be injection of the sclerotic coat at the margin of the cornea and from this area blood vessels extend into the deep layers of the cornea, becoming clinically obvious as a pink patch—the so-called *salmon patch*—or detected only with the aid of the slit lamp and corneal microscope. At the same time there is an exudation of inflammatory cells of the lymphocytic type into the deep layers of the cornea, causing haziness or *ground glass* appearance of the normally transparent membrane. The condition is very frequently associated with iridocyclitis which may be masked by the severity of the process in the cornea. The outcome is very variable. The attack may clear in a few weeks without damage to sight, or it may persist for many months and the patient may be prone to subsequent relapses. Even with severe attacks the damage to sight may be slight, but central opacities of the cornea are a common end result and vision may be grossly damaged in consequence. *Nerve deafness* resulting from involvement of the nerve endings of the 8th nerve in the internal ear is common among patients who suffer from interstitial keratitis, but

occurs rather later. It may also occur independently of corneal infection. The result may be bilateral progressive deafness which may become complete. Keratitis, nerve-deafness and characteristic deformities of the upper central incisors are sometimes called *Hutchinson's triad*. Other later effects of congenital syphilis are diffuse *interstitial orchitis* which may occur early in life, low-grade suppurative *otitis media* which may result in deafness without loss of bone conduction of sound, and effusion into both knee joints without pain or interference with movement, so-called *Clutton's joints*, which are found at any time from the ages of 5 to 18. Between the ages of 8 to 14, and sometimes earlier, these children may develop gummatous osteo-periostitis of the long bones, particularly the tibiae. The pathology of this condition is the same as that which occurs in adults, but the process is often widespread and may involve the whole length of the bone. Thickening of the tibiae is commonly most marked on the anterior surface of the middle third of the bone giving a forward convexity and appearance of curvature of the bone, the so-called *sabre-shaped tibia*. There is no true curvature of the bone because the gummatous process strengthens rather than weakens the cortex. In the early years of life there may be areas of localised thickening of the bones of the vault of the skull—so-called *periosteal nodes* or *Parrot's nodes*.

Congenital syphilis may not only cause anaemia and marasmus in infants and young children, but also delay in development and proneness to intercurrent infections in infancy and later years. The visceral and nervous affections of congenital syphilis are described in other sections of this book. Aortitis is rare as the result of congenital syphilitic infection.

(3) **STIGMATA**.—Scars and deformities result from the lesions which have been described. Facial disfigurement may be due to several causes. Severe and prolonged rhinitis may result in failure of normal development of the bones which surround the nasal cavity. Thus, flattening of the bridge of the nose may give the deformity known as *saddle-nose*; under-development of the superior maxilla may make it appear that the mandible is over-developed—so-called *bulldog jaw*; healed periosteal nodes of the frontal bone may give abnormal prominence of the forehead—*frontal bossing*; and the combination of these deformities is sometimes called the *bulldog facies*. Corneal scarring with empty blood vessels at the periphery of the cornea, rhagades, sabre-shaped tibiae, perforations of the palate and nasal septum, scars and deformities of the throat and tissue-paper scars of the skin are all common stigmata. The fundus oculi may show the changes of old healed choroiditis. The upper central incisors of the permanent dentition may show narrowing at the cutting edge, as compared with the width of the tooth at the gingival margin, together with curving of the margins, antero-posterior thickening and, in some cases, a crescentic notch at the cutting edge—so-called *Hutchinson's teeth*. Less often the 1st lower molars show a dome-shaped deformity of the grinding surface to which are attached the undeveloped cusps in the form of four small projections—so-called *Moon's molars*. These dental dystrophies result from the effect of severe syphilitic infection upon the developing buds of these teeth at or soon after birth.

Diagnosis.—If there are bullous lesions or other moist lesions *T. pallidum* can usually be found without difficulty. Scraping of the dry lesions of the skin may also make it possible to find the organism. The results of serological tests must be interpreted with reserve in the first weeks of life. Infants with negative serological tests may be suffering from active syphilis. On the other hand, non-syphilitic infants may give positive serological tests for syphilis if the mothers' tests are positive, due to the fact that they are suffering from long-standing infection or have been treated for early infection late in pregnancy. In cases of doubt antisyphilitic treatment should be withheld and quantitative tests should be repeated at weekly intervals. If the infant is not infected the strength of the test declines progressively to negative, usually within a few weeks and certainly within a few months. If the strength of

the reaction fails to decline or increases over a period of weeks, infection is probable. Confirmatory evidence can usually be obtained from physical examination and from radiographic changes in the long bones which are present very early.

Provided that the possibility of syphilitic infection is remembered the diagnosis should not present great difficulties. The bullous rash may be confused with pemphigus neonatorum, but the former appears earlier and is nearly always found on the palms and soles. Lesions in the napkin area may be mistaken for a napkin rash, but the latter is brighter red in colour and does not extend into the folds of groins and buttocks. The rashes of early congenital syphilis are nearly always associated with other signs.

Treatment.—**PREVENTIVE**—The prevention of transmission to offspring is primarily a matter of prevention of infection of mothers. The precautions to be observed in relation to the marriage of syphilitics and the cohabitation of those who become infected after marriage have been described. Most cases of transmission result, however, from undiagnosed and unsuspected infection, and for this reason all pregnant women should be fully examined and tested serologically during pregnancy. This precaution does not give absolute protection because of the possibility that the mothers may be incubating syphilis when examined or that they may be infected later, but it has certainly prevented many cases of congenital syphilis. Treatment of the syphilitic pregnant woman will almost certainly prevent transmission of infection. In the days of prolonged chemotherapy with arsenicals and bismuth it was the general experience that treatment begun before the end of the fourth month of pregnancy and continued throughout pregnancy nearly always protected the fetus. Treatment begun later or interrupted for any reason was less certain in its effects but still provided a degree of protection corresponding to the amount and duration of the treatment administered. In this respect penicillin has proved a very important advance in efficacy of treatment. Adequate dosage at any stage of pregnancy may be expected to ensure freedom of the offspring from infection in 98 per cent. of the cases. A convenient method is to give the mother a daily intramuscular injection of 600,000 units of procaine penicillin in oily or watery suspension for 10 days, the total dosage being 6 mega units. It is a reasonable precaution to repeat this course of injections of penicillin in succeeding pregnancies even though evidence points to the fact that the mother is already cured.

CURATIVE—There is no justification for treating the newly-born infant of a syphilitic mother for syphilis as a precautionary measure without first confirming the diagnosis. In cases of difficulty the correct diagnosis can always be made with certainty by waiting awhile and the infant is not likely to suffer in consequence. On the other hand, to assume the diagnosis and treat establishes the necessity for prolonged observation, frequent tests of the blood and tests of the cerebrospinal fluid. At the same time a lifelong stigma is attached to the patient, resulting in much unhappiness to everyone concerned. All of this may well be quite unnecessary.

When the fact of infection has been established, the infant should be treated with injections of penicillin, which is well tolerated and very effective. Various schemes of dosage have been recommended, the following is easy to give and efficacious.

Total dosage may be calculated at the rate of 200,000 units of penicillin per pound of body weight. Injections may be given intramuscularly every 3 hours day and night, but missing one dose at night, and administration should be spread over 10 days. Thus for a child of 7 pounds weight the total dosage would be 1,400,000 units, the daily dosage 140,000 units and the individual dose 20,000 units. Alternatively, 150,000 units of procaine penicillin suspension can be given intramuscularly each day for 10 days.

The results of such treatment in cases of early congenital syphilis are so good that further treatment is usually not required. Spirochaetes disappear from surface

lesions within a matter of hours, lesions heal promptly and serological tests for syphilis usually become negative after periods varying from a few weeks to 4 months and thereafter remain negative. It is rare to find pathological changes in cerebrospinal fluid tested 6 months to a year after treatment.

In the event that some indication for further treatment arises, a further course of injections of penicillin can be given with the likelihood of a good result.

In cases of late congenital syphilis the treatment is similar with dosage of penicillin based in the same way on body weight. The results are good but it is to be anticipated that in a number of these cases serological tests will remain positive in spite of treatment, and this is not necessarily an indication to continue treatment. On the other hand, evidence of clinical or serological relapse, as already defined, or of continuing activity of infection of the central nervous system, as shown by a persistent excess of lymphocytes and excess of protein in the cerebrospinal fluid, call for more intensive treatment.

Observation after treatment should be prolonged and certainly should continue until growth ceases, for, although the results of treatment are excellent, there are likely to be occasional failures. Provided that the patient remains clinically well with, in the case of early infection, negative serological tests, the tests of the cerebrospinal fluid need not be repeated if they are negative at the end of 1 year after treatment.

Certain of the late manifestations appear to run their course irrespective of treatment. Interstitial keratitis is a case in point. Antisyphilitic treatment should certainly be given because the patient is suffering from systemic infection, but additional local treatment is required for the eye to prevent damage to sight. The process is ultimately self-limiting and the administration of *cortisone* holds the inflammatory process in check until spontaneous cure results, reducing residual damage to a *minimum*. The drug may be given systemically, or topically by drops, ointment or subconjunctival injection. The method of choice seems to be the use of drops because it is effective, economical and comfortable for the patient. The drug is supplied as a suspension of 25 mg. of cortisone acetate in 1 ml. of normal saline with 1.5 per cent. of benzyl alcohol added as a preservative. The suspension is used in a 1 : 5 dilution, to avoid irritation of the eye. Drops are instilled 2-hourly for the first 24 to 48 hours, then 4-hourly and later twice daily as a maintenance dose. Instillation of 1 per cent. atropine solution is continued at the same time, at intervals of 4 hours. The symptoms are remarkably relieved. If administration is stopped too soon, relapse results. Deafness due to involvement of the 8th nerve is another condition which is likely to be progressive in spite of treatment.

TOXIC EFFECTS OF ARSPHENAMINE PREPARATIONS.—Local.—An intravenous injection of any arspenamine preparation or, particularly, of oxaphenarsine, may cause thrombosis of the vein into which it is injected; this is not a serious complication, but precludes the use of the vein for subsequent injections. Escape of the arsenical solution around the vein causes agonising pain, and swelling and infiltration of the tissues, which may go on to sloughing. This complication should be avoided by careful technique. Such an injection should never be given until the operator is quite certain that the end of the needle is lying freely in the lumen of the vein, as shown by free reflux of blood into the syringe when the plunger is withdrawn.

General.—All these compounds tend to damage capillary endothelium. Patients who have died as a result of injections of an arspenamine have been found to have blockage of cerebral capillaries with small surrounding haemorrhages, haemorrhagic nephritis, haemorrhages into lung alveoli, submucous petechiae and ecchymoses in stomach and bowel, and, in a comparatively few cases, degeneration and necrosis of liver cells.

Toxic effects are manifested by various clinical syndromes which require detailed description. This list is a comparatively long one, but some of the reactions are

preventable, and most are mild and infrequent, so that they do not preclude the routine use of these remedies. They may appear early or late in the course of treatment, as follows :

During or immediately after the injection.—(1) Vasomotor disturbances, also known as anaphylactoid symptoms or nitritoid crises; (2) urticaria; (3) syncope and (4) pain in the gums and teeth.

Following the injection, usually in a few hours, and occurring generally on the same day.—(5) Rise of temperature and headache; (6) vomiting, diarrhœa, pain in the back and cramp in the legs; (7) herpes labialis.

At various times from a day or two to a month or longer after the commencement of a course of injections.—(8) Albuminuria; (9) stomatitis; (10) persistent headache, lassitude, loss of appetite, loss of weight and insomnia; (11) dermatoses; (12) jaundice; (13) arsenical encephalopathy; (14) various blood dyscrasias; (15) polyneuritis.

(1) The *vasomotor symptoms* simulate those of anaphylaxis; they are rare after deep subcutaneous or intramuscular injections. The conjunctivæ become suffused, the face becomes flushed, and the tongue and lips may swell; there may be respiratory distress and the patient may become unconscious. As a rule the symptoms last for about half an hour, but in occasional cases recovery is not complete for a number of hours. Some patients are peculiarly susceptible to this reaction but it may be produced in other cases by too rapid administration or, it is said, by injecting the drug before solution is complete. All these remedies should be injected slowly, except oxophenarsine which does not produce this reaction and should be injected rapidly to prevent venous thrombosis. If precautions fail to prevent the reaction the drug should be changed to oxophenarsine given intravenously or sulpharsphenamine deep subcutaneously. For the immediate treatment of the reaction intramuscular injection of 10 minims of solution of adrenaline hydrochloride (1 in 1000) has been found to be effective. (2) *Urticaria*.—A severe vasomotor attack is sometimes followed by more or less generalised urticaria. (3) *Syncope*.—A feeling of faintness during the injection, or immediately after it, may be merely a precursor of vomiting or due to fear. Occasionally, however, the patient may become unconscious, pale and almost pulseless; fatal cases have been reported. Such an attack usually yields to ordinary restoratives, but may be very alarming for a time. (4) *Pain in the gums and teeth* is probably part of the vasomotor reaction. Some patients complain of a peculiar taste in the mouth, like garlic, or the smell of ether, during the injection. This also is probably a minor manifestation of the vasomotor reaction; it is said to be more common when concentrated solutions are used for injection. (5) *Rigor, rise of temperature and headache* are most common after the first injection. The temperature seldom rises above 101° F. and the reaction is not necessarily of serious significance. If, however, the symptoms recur after successive injections and increase in severity, arsenicals should be discontinued. (6) *Diarrhœa and vomiting* are unlikely to occur unless there have been indiscretions in diet or errors of technique. The patient is usually well by the next day. These symptoms may sometimes be prevented by ensuring that the patient fasts for 2 hours before each injection. (7) *Herpes labialis* may follow the febrile reaction. (8) *Albuminuria* is rare. It is more likely to follow the use of mercury and bismuth. (9) *Stomatitis* is seldom due to arsenical remedies, but there is support for the view that the tendency to this complication, which is shown by patients on treatment with mercury or bismuth, may be enhanced by the concurrent use of arsenicals. (10) *Persistent headache, lassitude, loss of appetite, loss of weight and insomnia* are symptoms of intolerance. They are not very common, but indicate the necessity for stopping the treatment. If they are disregarded major complications of treatment are very likely to follow. (11) *Dermatoses*.—In addition to urticaria and herpes, various affections of the skin

result from administration of organic arsenicals and one of them is a serious and dangerous condition. The mildest presents as slight pruritus which may quickly disappear or may be prodromal to a serious complication. An early eruption is the condition which was called by Milian *erythema of the ninth day*. It appears from the seventh to twelfth day after the start of the treatment and within $\frac{1}{2}$ to 2 days of an injection. It is preceded by a rapid rise of temperature, to 101° F or higher, headache, backache, and sometimes vomiting and diarrhoea. These symptoms are followed by the appearance of a generalised scarlatiniform, morbilliform or polymorphic eruption, which fades in a few days with very slight or no desquamation. In severe cases it may be associated with or followed by jaundice. Prodromal fever and the absence of desquamation are important points of distinction from the more serious exfoliative eruption which indicates permanent sensitisation. It has been stated that treatment with arspenamine can be resumed after erythema of the ninth day has subsided, but if this is done at all extreme caution should be exercised. The most severe dermatosis, usually called *arsenical or exfoliative dermatitis*, is relatively uncommon. It starts as a punctiform erythema which quickly spreads over the body and is accompanied by most intense itching. It often becomes vesicular and desquamation of the surface epithelium follows. So serious are the potential effects of this complication that the complaint of generalised irritation of the skin or the appearance of a rash which shows vesicles or desquamation in the course of treatment with arsenical injections contraindicate further use of these remedies, even though recovery is prompt. Careful questioning as to irritation of the skin and observation for the first signs of erythematous rash will often give timely warning of the complication and, by stopping the administration of more arsenic, may save the patient from a severe attack. Patients suffering from exfoliative dermatitis are very prone to secondary infection of the denuded areas of skin and to intercurrent infections of the respiratory system. They may also suffer from blood dyscrasias. Illness is often prolonged and severe and may be fatal. The patient should be confined to bed and protected from cold. Excellent results have followed the administration of dimercaprol, which should be used in all such cases. Its value in arsenical poisoning is that it competes with tissue cells for the arsenic and perhaps detaches some of the arsenic which has already combined with tissue proteins. It is injected intramuscularly in the form of a 5 per cent solution of dimercaprol and 10 per cent benzyl benzoate in arachis oil. Each ampoule contains 100 mg. and injections are given as follows:

1st Day	4 ampoules at intervals of 4 hours
2nd, 3rd and 4th Days	2 ampoules—1 in the morning and 1 at night
5th and 6th Days	1 ampoule
	Total—1200 mg

If further treatment is required the course may be repeated after an interval of 1 week.

In this dosage toxic effects are slight or negligible, but it is important to ensure that the injection is made into the muscle and not into subcutaneous tissue for otherwise local abscesses may occur. Dimercaprol is often remarkably effective in halting the progress of the complication and facilitating recovery of the skin. The diet should be simple and the fluid intake maintained. Calamine lotion or a bran bath may be applied locally. Areas of skin which are moist after exfoliation should be covered with sterile dressings. (12) *Jaundice* following injections of arspenamine preparations was known to be a complication of arsenical therapy for 30 years before its true cause was recognised. In most cases the condition is mild, the patient complains of anorexia and malaise and shows a variable degree of jaundice with enlargement of the liver and perhaps the spleen, with clay-coloured stools and highly coloured urine. Tests show moderate to severe impairment of liver function. Occasionally

the condition is much more serious, with severe epigastric pain restlessness and delirium followed by death. The changes found in these rare cases have been extensive degeneration and necrosis of liver cells with round celled infiltration of the supporting connective tissue multiple subserous hæmorrhages and, frequently hæmorrhages into lung alveoli. Jaundice may commence during a course of injections or be delayed for several months after the completion of a course. The incidence of this complication showed a very great increase in the Armed Forces during the War of 1939-1945. In 1943 it was suggested that it might be due to an infective agent, like that in the icterogenic batches of yellow fever vaccine which had been responsible for many cases of jaundice at one period of the war, and that this agent might be strongly resistant to heat and might be contained in minute amounts of blood left in syringes after intravenous injections of arsenical compounds. Later it was shown that the methods of sterilisation employed in many treatment centres were ineffective even against pyogenic organisms. It was then found in military hospitals that post arsphenamine jaundice could be very greatly reduced if not entirely eliminated by a very strict regimen of syringe sterilisation. Homologous serum jaundice has since been shown to follow not only arsenical injections, but injections of bismuth penicillin insulin, gold, acriflavine and other substances. It is fully preventable by strict precautions in the sterilisation of syringes and needles and careful technique of injection. (13) *Arsenical encephalopathy*—With this complication patients show severe cerebral symptoms with headache followed by mental confusion, epileptiform convulsions and coma, ending in death in a large proportion of cases. The condition has been rare with ordinary schemes of treatment employing standard dosage with injections once or twice a week. The symptoms usually begin from 2 to 5 days after the second injection, but this is not an invariable rule. Necropsy reveals œdema of the brain with dilatation of capillaries capillary hæmorrhages and some times larger ring shaped hæmorrhages. If the patient survives for some time after the onset of the attack, areas of demyelination may be found in the white matter of the brain. It has been shown that hæmorrhagic encephalopathy is more apt to occur in females than in males, and especially towards the end of pregnancy. It is much more frequent in patients treated by intensive methods of treatment, employing daily injections of oxophenarsine which were used during the War of 1939-1945, and was in fact, the chief danger of this form of treatment. Apart from the fatal cases with convulsions and coma milder forms of encephalopathy occurred in a number of these cases in the form of severe headache and mental confusion. The value of treatment of this complication is doubtful, but various methods have been recommended. If it is to be of value, treatment should be instituted as quickly as possible after the onset of the symptoms. It has been claimed that daily lumbar puncture with removal of 15 to 20 ml of cerebrospinal fluid, and bleeding to 15 to 20 oz have been effective. In 1945 Ransome, Paterson and Gupta reported excellent results from nursing patients in the sitting posture, with full sedation to control fits. Lumbar or cisternal puncture was performed at the outset and repeated if coma seemed to deepen. Eagle (1946) claimed good results from the prompt use of dimer caprol. (14) *Blood dyscrasias*—Three disorders of the blood forming organs have been described but all of them are rare. They have followed treatment with sulpharsphenamine relatively much more often than treatment by other arsphenamine preparations. They are thrombocytopenia, granulocytopenia and aplastic anemia. Some times they are found in association with arsenical dermatitis. The symptoms, signs and treatment of these conditions are described elsewhere in this volume (see p 738). (15) *Polyneuritis* is extremely rare with standard methods of treatment. It was a common complication of intensive methods of arsenotherapy.

TOXIC EFFECTS OF OXOPHENARSINE.—The toxic effects are very similar to those following administration of the arsphenamine compounds except that vasomotor symptoms and similar immediate reactions do not occur.

TOXIC EFFECTS OF TRYPARSAMIDE—The main risk is of amblyopia, and for this reason the patient's visual fields were usually tested and charted by an ophthalmologist before treatment was started, and at intervals of a fortnight during treatment. It was essential that treatment should be stopped at the first indication of subjective disturbance of vision.

TOXIC EFFECTS OF ACETARSOL AND ACETYLARSAN—Toxic effects were usually mild. Acetarsol sometimes caused gastro intestinal disturbance if taken too near a mealtime. Slight erythema occurred sometimes and, very rarely, severe dermatitis of the exfoliative type.

TOXIC EFFECTS OF MERCURIAL PREPARATIONS—Mercury may cause stomatitis, nephritis, colitis, general malaise and dermatitis.

Stomatitis can usually be prevented by care. The patient's teeth and gums should receive attention before treatment is begun and he should brush his teeth night and morning. Potassium chlorate is a useful antiseptic in these cases and may be used as a mouthwash or incorporated in a dentifrice. The onset of stomatitis is marked by salivation and pain, tenderness and swelling of the gums. The mucous membranes are rather livid in appearance. Oral fever is pronounced and precedes the onset of ulceration. The mercury must be stopped and treatment applied to the mouth in the form of local applications of potassium chlorate or peroxide of hydrogen. An astringent mouthwash should be employed. In severe cases injections of dimercaprol should be given. *Nephritis* rarely results from moderate doses of mercury, but the possibility of damaging effect upon the kidneys should be remembered in cases of patients suffering from renal disease. *Colitis* is extremely uncommon as the result of ordinary dosage of mercury but has occurred in patients with an idiosyncrasy to the metal. It is a serious condition and may be fatal. *General malaise* is apt to result from too heavy dosage, it is always advisable to keep a close watch on the patient's weight and general condition when this kind of treatment is used. *Dermatitis* as a result of mercurial treatment is very rare.

AMBROSE KING

YAWS

Synonyms—Frambæsia, Frambæsia tropica, Pian, also many vernacular names such as Parangi (Ceylon), Bubas (Brazil), Coco (Fiji) etc.

Definition—A contagious, inoculable, tropical disease caused by *Treponema pertenue*. The primary lesion is of non venereal origin and is followed by the secondary stage consisting of an eruption of typically "granulomatous" papules. The tertiary stage, occurring a few or many years later, is characterised by destructive lesions.

Ætiology—Yaws is essentially a disease of indigenous populations of tropical countries. Europeans are rarely affected. It is prevalent in the West and East Indies, Ceylon, the Philippines, Oceania and New Guinea and parts of tropical Africa and South America. Infection usually occurs in childhood, although a few adults escaping infection then may contract it later. The disease is not transmitted congenitally, and infection is generally regarded as occurring only once in a lifetime. Both sexes are attacked. The cause is *T. pertenue*, which is morphologically indistinguishable from the spirochæte of syphilis, on animal inoculation, however, constantly different reactions have been observed. The similarity of yaws and syphilis is greatest in the tertiary stage. Bejel, the non-venereal syphilis of the Bedouin Arabs, has certain epidemiological and clinical similarities to yaws. *T. pertenue* enters the skin through minor abrasions, most commonly on the limbs and especially the legs. The causal organism of the Central and South American disease *pinta* is also morphologically indistinguishable from the spirochæte of syphilis.

Pathology—The primary and secondary lesions are characterised by interpapillary down growths of epidermis into the corium. There is also œdema and infiltration

with polymorphonuclear leucocytosis and plasma cells both in the proliferated epidermis and in the corium. Spirochaetes are more numerous where the cellular infiltration of the epidermis is most pronounced, but they are also present in the adjacent corium. The tertiary lesions are characterised by necrosis and ulceration with granulation tissue and dense fibrous tissue formation. Giant cells are frequently present, but spirochaetes are not numerous. Though peri-vascular cellular infiltration and vascular endothelial proliferation are usually said not to occur in yaws lesions, there are no generally reliable histological criteria for the differentiation of yaws and syphilitic skin lesions in man.

Symptoms.—The incubation period in man is 4 weeks or longer (in monkeys 3 weeks), and may be accompanied by mild general symptoms.

The primary lesion resembles the typical secondary lesions but is often larger. It is most frequent on the lower limb, is usually single and extragenital, and may heal before the secondary eruption appears or outlast it. The adjacent lymphatic glands may be enlarged.

The *secondary stage*, which may appear within 3 weeks of the primary lesion, may be heralded by irregular intermittent fever, headache, bone and joint pains, often worse at night, and a characteristic more or less generalised papular eruption. This commences as small, yellowish papules, which increase in size or coalesce to form larger lesions. The stratum corneum is shed, exposing a granular surface of minute pinkish elevations, separated by a whitish groundwork. Serum containing treponemata exudes and dries, forming a yellowish crust, which later may become discoloured and polished, especially in the case of less active lesions. Pus is not usually present. Healing occurs sooner or later, often leaving but little scarring, although hyperpigmentation, which later disappears, may be seen. The lesions may itch, and, although not very painful, are sensitive to minor irritation, such as flies. The distribution is general, but the trunk is often relatively spared. The body orifices and the soft skin of flexures are particularly involved. Successive crops may appear for from 2 to 3 years. Other types of skin lesion, pathologically related to those just described, are often seen, but usually typical secondary lesions are also present. These include darker macules, desquamation and acuminate papules. General enlargement of the lymphatic glands is often found. The eruption of a yaw on the sole, clavus or crab yaws, is particularly painful, and may appear many years after the earlier lesions have healed. Other plantar and palmar changes consist of thickening and desquamation of the epidermis. Yaws papules may also develop on the buccal mucous membrane. Bone lesions are frequent during this stage, and are characterised by swellings. Periosteal deposits and rarefied foci in these deposits and in the cortex are seen radiographically. Sabre-tibia may develop, but destructive bone lesions do not occur. Multiple dactylitis is frequent. Ganglia and synovitis with free fluid are seen. Goundou belongs to this stage. All secondary lesions heal spontaneously, although bony thickening may remain. The general health is not usually seriously affected.

The *tertiary stage* may be reached within a year of the healing of secondary lesions, or after a quiescent period of many years. Lesions at this stage are characterised by tissue destruction and ulceration. In the skin superficial ulceration or deep gummatous-like processes may occur, which on healing leave hyperpigmented atrophic scars and occasionally contractures. In the bones, swellings with ulceration associated with bony necrosis ("gummata"), spontaneous fractures, deformities of the digits, periostitis, nodes, synovitis and arthritis are seen. Destructive processes in the mouth and nose may lead to palatal perforation and to gangosa. Epidermal thickening, erosions, fissures and coarse desquamation occur on the palms and soles, some of which may return to normal, but others result in atrophic changes and pigmentation. Juxta-articular nodes, chronic bursitis and patchy depigmentation of the skin are also met with.

Complications and Sequelæ—In severe tertiary cases with many lesions, cachexia may result. Intercurrent diseases may be present. In Fiji and Haiti aneurysm and lesions of the central nervous system have been attributed to yaws, but the evidence is not convincing.

Diagnosis—In localities in which yaws is prevalent there is usually no difficulty in diagnosing the early lesions, but congenital and acquired syphilis, bejel and bromide rashes may occasionally call for consideration. *Treponemata* can usually be found in serum from early lesions. The differentiation of tertiary lesions from syphilis may be impossible on clinical or pathological evidence, and a history of yaws in the past may be the only guide. Cutaneous leishmaniasis, blastomycosis, leprosy and tuberculosis may lead to confusion. The Wassermann and Kahn reactions are positive in yaws and syphilis after the first few weeks. The absence of visceral, vascular and central nervous system lesions in yaws and its ready response to modern arsenical and bismuth preparations and antibiotics may help to differentiate the two diseases.

Prognosis—All secondary lesions heal spontaneously in a few months or years, and probably some cases become spontaneously cured and develop a negative Wassermann reaction. Yaws is rarely fatal, most deaths being due to intercurrent disease. Modern therapy is effective. In tertiary lesions more intensive treatment is required to produce healing and here, too, spontaneous cure probably occurs although less readily.

Treatment—**PROPHYLACTIC**—Avoidance of direct contact with cases of yaws is the basis of prophylaxis. Ordinary cleanliness, and the covering of cuts, abrasions and ulcers with suitable dressings to prevent contact with infective material and flies are important.

CURATIVE—As in the treatment of syphilis, trivalent arsenicals, *e.g.* neoarsphenamine, bismuth compounds and penicillin are of great value. To ensure complete cure, serological follow up is essential. In practice in yaws areas therapy is intended to reduce infectivity ('blanchiment'). For this from 4 to 6 intravenous injections of neoarsphenamine (0.05 g per 10 lb to maximum dose of 0.75 g) with from 4 to 6 intramuscular injections of a bismuth salt *e.g.* bismuth salicylate (0.02 ml of 10 per cent. suspension in oil per 10 lb to maximum dose of 3 ml) should be given at weekly intervals by mobile and static treatment units. Twelve months after injections of either of these preparations the Jamaican Yaws Commission (1935) found about 50 per cent of primary and secondary cases had negative serological reactions. Other bismuth or arsenical preparations may be used. Following bismuth administration stomatitis may develop in unhealthy gums. Antibiotics are now extensively used in mass campaigns and in the treatment of individual cases. Procaine Penicillin G in oil with 2 per cent aluminium monostearate is the most widely recommended. Hill gives the following dosage regime. Adults total dose of 2.4 million units given intramuscularly into the buttock in two equal doses 3 to 5 days apart. Children of 5 to 12 years total dose of 1.2 million units given in two equal doses as above. Children under 5 years, total dose of 0.3 million units given as a single injection.

Chlortetracycline and chloramphenicol have been used successfully in doses in adults of 1.0 to 2.0 g per day given daily for a fortnight. Shorter more concentrated dosage regimes have not been so successful. Oxytetracycline is active in doses of 3.0 g the first day followed by 2.0 g daily for the next 2 to 5 days.

Treatment with penicillin is quick, reasonably cheap and at least as effective as with the oral antibiotics. It is regarded as the ideal for mass treatment campaigns.

In tertiary yaws therapeutic response is less rapid. Up to date there has been no tendency for syphilis to flare up where yaws has been reduced.

Local treatment is necessary if there are extensive ulcers and lesions involving the soles of the feet. Deformities associated with periostitis and contractures may need plastic surgery.

GOUNDOU

Synonyms—Anakhre, Gros Nez, Dog Nose

Definition—Symmetrical bony tumours of the sides of the nose commencing during the secondary stage of yaws

Ætiology—This condition is found wherever yaws is prevalent, but has been reported most often from tropical Africa, especially in the west. It is seen in children and adults

Pathology—There is thickening of the periosteum with production of spongy tissue in which are fibrosis and perivascular plasma cell infiltration. The bony tissue is usually bounded by a thin layer of cortical bone. This hypertrophic osteitis involves the nasal process of the superior maxilla. In marked cases the tumour may encroach upon the nasal passages, orbit or palate

Symptoms—Pain in the bones and headache may occur in the early stages but later these subside. The paranasal swelling on one or both sides increases outwards and may become large enough to obstruct vision. Facial deformity may be the only symptom but nasal obstruction may also result. The overlying skin is not implicated. Sometimes similar tumours elsewhere on the superior maxilla, or on the inferior maxilla and other yaws bone lesions may also be present

Diagnosis—In yaws communities the paranasal swellings are characteristic, but in isolated cases differentiations may be needed from syphilitic osteitis, leontiasis ossea and possibly acromegaly

Prognosis—Marked deformity is rare. Some reduction in the size of the lesions in early cases may occur spontaneously or after treatment

Treatment—Energetic anti yaws therapy is indicated in early cases, and surgical removal of the bony tumour in advanced ones

GANGOSA

Synonym—Destructive Ulcerating Rhino pharyngitis

Definition—An ulcerative process of tertiary yaws resulting in destruction of the palatal and nasal structures

Ætiology—This condition is probably to be found wherever yaws is endemic. Its preoccurrence in the Pacific Ocean Islands and the East Indies has been stressed. It may commence in older children and adults

Pathology—The process begins with ulceration of the palate or in the nose, and is followed by destruction of soft tissues and bone. The histopathology is that of tertiary yaws

Symptoms—Pain, purulent discharge and foul odour accompany the ulceration mentioned above. The amount of destruction produced varies from a small perforation of the soft or hard palate, or some falling in of the nose, to complete destruction of the palate, nose, nasal contents and adjacent tissue of the cheeks and orbit so that the roof of the nasal cavities, pharynx and tongue are exposed. Arrest of the process either spontaneously or following therapy may occur at any stage. The larynx is probably not affected

Diagnosis—In yaws communities this is usually easy, but differentiation from American dermal leishmaniasis, syphilis and leprosy may be necessary

Prognosis—The progress of the destruction and healing is usually slow, and although the response to adequate treatment is good, tissue losses remain. Death may result from general exhaustion, sepsis, insufflation pneumonia or other intercurrent disease

Treatment—Energetic anti yaws therapy is indicated and intercurrent disease may need treatment

JUXTA-ARTICULAR NODES

Definition.—Multiple, painless, fibrotic nodules occurring in the vicinity of joints and bony prominences in the later stages of yaws.

Ætiology.—This condition is probably found wherever yaws is prevalent, and has been reported from most tropical countries. It is rare in childhood and is characteristically seen in elderly people often together with chronic pre-patellar bursal enlargement. Similar lesions are occasionally met with in late syphilis and in bejel.

Pathology.—The nodules consist of hard, greyish-white, avascular fibrous tissue, in which may be opaque yellow spots and occasional areas of necrosis. Foci of chronic inflammatory cells are found microscopically; endarteritis is said not to occur but treponemata have been demonstrated in them. The tumours have no capsules, and merge into the neighbouring connective tissue.

Symptoms.—The nodules appear as small round multiple tumours in the subcutaneous tissue about joints and bony prominences, especially the knee, elbow and over the femoral trochanter. Only a few are present at any one situation; they are painless, firm and even cartilaginous in consistency, and only rarely break down and ulcerate. They are usually freely movable under the skin, but later some attachment to the skin at the most prominent point may occur. Their development is slow, and the nodules may resolve spontaneously or remain stationary. Their usual size is 1 to 2 cm., but some may become much larger.

Diagnosis.—Differentiation from syphilitic, rheumatic and onchocerca nodules may be necessary. Biopsy may be of assistance. In onchocerciasis the tumours are often softer, and embryos may be demonstrated in aspirated fluid; on section they are loculated, and filaræ and embryos are present.

Prognosis.—The nodules may cause some discomfort at points of pressure, but do not endanger life.

Treatment.—If necessary, troublesome nodules may be excised. Intensive anti-yaws therapy may cause resolution in some and regression in others.

LEPTOSPIROSIS

Since the causative organism, *Leptospira icterohæmorrhagica*, was first demonstrated in Japan by Inada and Ido in 1915, leptospirosis icterohæmorrhagica has been recognised in many different countries. The earliest observations indicating that strains of leptospira other than the classical leptospirosis icterohæmorrhagica strain might produce disease in man was made two years later in Japan when *L. hebdomadis* was shown by Ido, Ito and others to cause Japanese 7-days' fever or Nanukayami disease. Subsequently several strains differing in antigenic structure were discovered in the Dutch East Indies and Malaya. In Europe swamp fever was recognised as a leptospirosis caused by *L. grippo-typhosa*, and in 1934 *L. canicola*, which commonly affects dogs, was shown to produce leptospirosis in man. More recently several new strains have been isolated in Australia, the Argentine and Palestine. Schüffner classified the leptospiroses pathogenic to man on the basis of different antigenic structure as revealed by serological reactions and animal inoculations, the clinical picture, epidemiological considerations and geographical distribution. Many different strains are recognised, and these are separated into two groups, i.e. those capable of producing jaundice and those which fail to do so, but it should be remembered that even in classical leptospirosis icterohæmorrhagica only 50 per cent. of patients develop jaundice. The clinical picture in leptospirosis caused by any of these strains includes conjunctival congestion, fever, prostration, severe headache and generalised muscular pains; meningeal symptoms and rashes may also develop. A neutrophil leucocytosis is characteristic. The outstanding difference is in prognosis, for while many cases

of classical leptospirosis icterohæmorrhagica die, patients infected with other strains almost invariably recover. Early blood culture, inoculation of guinea-pigs with blood or urine, serum agglutination reactions and other serological tests are essential to establish the diagnosis of leptospirosis and determine the strain of leptospira implicated.

I LEPTOSPIROSIS ASSOCIATED WITH JAUNDICE

Four strains pathogenic to man are included in this group

(1) The classical Weil strain, *L. icterohæmorrhagica*, is cosmopolitan in distribution and lethal to guinea pigs. The natural reservoir is *Rattus decumanus*, and it is known that in many different countries rats of this species pass *L. icterohæmorrhagica* in large numbers in the urine, these organisms infect man through skin abrasions or via the nasal mucous membranes during submersion in contaminated water. Only rarely the disease is acquired from infected dogs and cats.

(2) Akiyama A strain is similar to *L. autumnalis* of Japan and the Rachmat strain of the Dutch East Indies. The natural host is *Apodemus speciosus* in Japan where it has an autumnal prevalence.

(3) The Salnem strain, or *L. pyrogenes*, of the Dutch East Indies is probably identical with the Zanoni strain, which is one of the two leptospires responsible for leptospirosis amongst the cane-cutters of Queensland, Australia, in the rainy season. It has been found in a local species of rat—*R. culmorum*. The strain is lethal to guinea pigs.

(4) The Batavia strain is found only in Java where *R. decumanus* appears to be the reservoir host. It is less pathogenic for guinea-pigs than the other strains described above.

II LEPTOSPIROSIS WITHOUT JAUNDICE

A number of different strains pathogenic to man are included in this group. These include

(1) *L. hebdomadis* causes '7-days' fever in Japan. It is primarily an infection of the field vole, *Microtus montebelli*, and appears in the urine, which contaminates soil or food. It has recently been found in Sumatra in dogs and man.

(2) *L. grippo typhosa* gives rise to summer epidemics amongst field workers in Europe, but the reservoir host and mode of infection is unknown. The disease runs a benign course. It has also been isolated from patients with leptospirosis in the Andamans (Andaman B strain).

(3) *L. canicola* produces an epizootic in dogs, from which man acquires the disease by contact. It is most easily isolated and maintained in Syrian hamsters. In canicola fever, though jaundice is absent, the meningitic symptoms often appear more severe than in classical Weil's disease.

(4) The Pomona strain produces fever lasting 3 to 8 days, and has been isolated from agricultural workers in Queensland and in North Italy. It occurs after rain.

(5) The Ballico strain causes leptospirosis in Queensland on the cacao plantations after rain. It produces a mild fever lasting a week. It is lethal to guinea pigs and has been found in local rats.

LEPTOSPIROSIS ICTEROHÆMORRHAGICA

Synonyms—Spirochætal Jaundice, Weil's Disease; Spirochætosus icterohæmorrhagica.

Definition—An acute febrile disease with a world wide distribution, caused by *Leptospira icterohæmorrhagica*, and generally occurring in people with an occupational relationship to rats. In its typical severe form it is characterised by fever, profound

prostration, headache, generalised pains and acute muscular tenderness, conjunctival hyperæmia, leucocytosis, albuminuria, jaundice and a tendency to hæmorrhage. Subclinical infections may occur, and jaundice is absent in about 50 per cent of cases.

Ætiology—In 1886, Weil first directed attention to this disease, which is now associated with his name. In Japan it was well known amongst miners and labourers in the rice fields, and in 1915 Inada and Ido infected guinea-pigs with blood from human cases and demonstrated *L. icterohæmorrhagicæ* in the tissues. Later, rats (*Rattus decumanus*) were found to be the reservoir host, the leptospiras, which were localised in the kidney, escaped in the urine and often contaminated water, fungal slime and soil. In man infection generally occurs in people who work in rat-infested places, and follow occupations in which minor injuries and abrasions of the skin are common; this accounts for its incidence in sewer labourers, bargemen, canal and dock workers, fish and tripe cleaners, coal miners and farm labourers. In Great Britain the disease is recognised as an occupational one, for which compensation may be claimed under the Workmen's Compensation Act. In trench warfare troops may become infected. The disease may also be acquired via the nasal passages from infected water when bathing or during immersion accidents, which mode of infection is particularly common in Holland.

Pathology.—(1) **MORBID ANATOMY**—In fatal cases there is an acute hepatitis with jaundice, while parenchymatous degeneration of the tubular epithelium of the kidneys, perhaps associated with hæmorrhages into Bowman's capsules, is characteristic. Large and small hæmorrhages are often scattered throughout the tissues and particularly affect the stomach, intestinal mucosa and the lungs.

(2) **ISOLATION OF THE LEPTOSPIRA**—*L. icterohæmorrhagicæ* may be isolated by blood culture in Fletcher's medium during the first week, or by injecting 5 ml of infected whole blood intraperitoneally into the guinea-pig up till the tenth day of the disease. In the cultures there is a time lag of 3 to 5 days before leptospiras are found, and of 5 to 8 days before they appear in the viscera or blood of inoculated guinea-pigs. Where meningeal symptoms develop leptospiras may be found in the cerebrospinal fluid, and they are often demonstrable in the urine after the second week.

(3) **SEROLOGICAL REACTIONS**—The agglutination reaction, using formalised cultures as advised by Schuffner, yields satisfactory results. Agglutinin appears in low titre about the fifth or sixth day, and rapidly increases during the second and third week of the disease, maximal titres up to 1/100,000 have been recorded. Agglutinins persist for many years after an attack, and multiple observations to determine an increase in titre may be necessary in cases in which the titre is low and residual agglutinin may have persisted from a previous infection.

Symptoms and Course—The incubation period varies from 6 to 12 days. In moderately severe cases presenting the classical clinical picture three stages are recognised: (1) a febrile stage, with sudden onset, (2) an icteric stage, associated with renal features, and sometimes hæmorrhage and (3) a convalescent stage, in which febrile relapses are common.

(1) **FEBRILE STAGE**—This generally lasts 6 to 8 days. As a rule the onset is sudden, with shivery feelings and definite rigor. Headache, nausea, vomiting, profound asthenia, backache, photophobia and generalised muscular pains are characteristic. So severe may the muscular pain and tenderness be that the patient cries out with agony on the slightest movement. Conjunctival injection is common and herpes with hæmorrhage into the vesicles not infrequent. The muscles of the limbs and the abdominal muscles are often exquisitely tender on palpation. There may be some enlargement of liver or spleen but often this is absent even in the icteric stage of the disease. A neutrophil leucocytosis is characteristic, the total count varies between 10,000 to 20,000 leucocytes per c. mm., and the neutrophils equal 80 to 85 per cent.

(2) **ICTERIC STAGE**—An icteric tinge of the conjunctivæ and lemon yellow tinting of the skin appear from the fourth to the sixth day, but are only found in about 50 per cent of cases. The jaundice gradually deepens and may become a deep orange in colour. A direct biphasic van den Bergh reaction develops, with well-marked hyperbilirubinæmia, in a recent series one patient whose plasma contained 56 units recovered, and another with a maximum value of 29 units died of cholæmia. With the onset of jaundice the urine becomes dark brown, and contains bile salts and bile pigments. The stools often contain excess of fat, which is adequately split, and are often pale brown or even white in colour, the result of a decrease of stercobilin.

Evidence of renal involvement is not infrequent and the urine, which is decreased in quantity, contains albumin, renal casts, pus cells and perhaps red blood corpuscles. As renal function fails the nitrogenous constituents of the blood increase and the blood urea attains high values. Anuria may ensue. Hiccough, Cheyne Stokes respiration, subsultus tendinum, delirium and coma are features common to cholæmia and uræmia, which are frequent causes of death. Skin petechiæ or purpuric patches sometimes appear and bleeding gums, hæmoptysis, hæmatemesis, melæna and hæmaturia may complicate the picture.

(3) **CONVALESCENCE**.—This generally commences in the third or fourth week by which time the renal and hepatic manifestations have subsided, but it is often 5 or 6 weeks before the patient is fit to leave hospital. Not infrequently in the third week a relapse of fever occurs, which may last from a few days to 3 weeks, it is generally unaccompanied by icterus or other severe symptoms.

Atypical Clinical Types These are frequent, and may or may not be associated with jaundice. They include

(a) **Anginal type**—The patient complains of fever, generalised pains and sore throat, and is usually diagnosed as influenza, tonsillitis or rheumatic fever. Unless jaundice develops or the occupation of the patient suggests the possibility of leptospirosis *icterohæmorrhagica*, laboratory investigations are not made and the true nature of the infection remains unrecognized.

(b) **Abdominal type**—There is fever, abdominal pain, vomiting and localised or generalised rigidity associated with acute tenderness of the abdominal muscles, the picture may resemble an acute abdominal condition, such as appendicitis, cholecystitis, pancreatitis or peritonitis. A neutrophil leucocytosis is present, and when hæmatemesis occurs, perforated gastric ulcer may be diagnosed.

(c) **Respiratory type**—There are physical signs of pulmonary consolidation resembling pneumonia, and hæmoptysis may supervene. Jaundice may never develop.

(d) **Meningeal type**—Not uncommonly leptospiral meningitis, with neck retraction, Kernig's sign, etc., may develop at the onset. Lumbar puncture reveals a clear fluid under increased pressure, containing neutrophil leucocytes, lymphocytes and perhaps monocytes, while leptospiras may be demonstrated by animal inoculation or culture. More rarely, chronic meningitis may supervene months after the acute stage of the disease has subsided, but notwithstanding this the cerebrospinal fluid contains pus cells and leptospiras.

Subclinical infections also occur in which people like sewer workers acquire a symptomless leptospirosis, there is no history of illness yet the blood shows definite agglutination against *L. icterohæmorrhagica*.

Diagnosis—Few diseases are more protean in their clinical manifestations or have remained for such long periods undetected in communities. Leptospirosis *icterohæmorrhagica* is not generally suspected until the patient develops jaundice and there is known to have been an occupational relationship to rats or a recent water immersion accident. An appeal to the laboratory under such circumstances will generally enable a delayed diagnosis to be made, either by isolating the leptospira

or by serological tests. Apart from jaundice, a history of possible contact with rat-infected material, the extreme prostration, the conjunctival injection and the severity of the muscular pain and tenderness, and the neutrophil leucocytosis, should arouse suspicion.

Prognosis.—Fatal cases are almost invariably jaundiced and die between the ninth and fourteenth day as a rule from cholæmia or uræmia. The mortality rate appears to vary in different outbreaks, but where the diagnosis is reasonably good it is about 9 per cent.

Treatment—**PROPHYLACTIC**—This includes the protection of bathing pools, abattoirs, fish shops, etc., from rats, and the immediate treatment and protection of any skin abrasions in people whose occupation brings them in contact with rat-infected material. Prophylactic vaccination is under trial. Nurses should be instructed to disinfect the patient's urine.

CURATIVE—Antileptospiral serum given repeatedly in large doses in the febrile period is recommended by some workers.

Penicillin, chlortetracycline and oxytetracycline in big doses may be effective if administered early.

Treatment is unsatisfactory in late cases.

Fluids and glucose should be administered orally, while intravenous glucose (5 per cent) is a useful adjunct to therapy in severe cases.

RELAPSING FEVER

Synonyms—Spirochætosis, Febris Recurrens, Spirillum Fever, Famine Fever.

Definition—A group of specific infectious fevers due to spirochætes (treponemata) and spread by lice or argasine ticks, characterised by a variable number of febrile relapses.

Ætiology—Relapsing fever occurs in many parts of the world and is often seen in epidemic form during wars and famines. It is rare in England, but occurs in parts of Europe including Russia, in Turkey, India, Cochinchina, Algiers, Egypt, Africa and the Americas it is not infrequent. All ages and both sexes are liable. The different varieties of the disease are caused by spirochætes demonstrable in the peripheral blood during the febrile paroxysms, and they may be divided into the lice-borne and tick-borne fevers. The varieties transmitted by lice include (1) European relapsing fever due to *Treponema recurrentis* (the old spirillum of Obermeier), (2) Northern African relapsing fever produced by *T. berberum*, (3) Indian or Asiatic relapsing fever caused by *T. carteri*, (4) North American relapsing fever attributed to *T. novyi*. The varieties transmitted by the argasine ticks include (1) Central African tick fever due to *T. duttoni* transmitted by *Ornithodoros moubata*, *O. erraticus* and *O. savignyi*, (2) Palestinian and Syrian tick fever caused by *T. sordianum* and transmitted by *O. papillipes*, (3) Persian and North-West Indian relapsing fever caused by *T. persicum* and transmitted by *O. papillipes* (*tholozani*) or *O. lahorensis*, (4) Spanish relapsing fever attributed to *T. hispanicum* and transmitted by *O. maroccanus*, (5) Central and South American relapsing fever due to *T. venezuelense* is transmitted by *O. venezuelensis* in Colombia and Venezuela, and by *O. talaje* in Panama, (6) Californian tick fever due to *T. turicata* and transmitted by *O. hermsi*. At present it appears somewhat doubtful whether the creation of the numerous species of spirochætes detailed above is justified on grounds other than those of convenience. Lice become infective about the sixteenth day, and remain so for about 1 month. Infection is probably conveyed by the feces, or after the louse has been crushed and the spirochætes liberated from the coelomic fluid, scratching may play an important part in transmission. Some ticks transmit infection during

the act of biting, in others, like *O. moubata*, the spirochaetes are liberated in the coxal fluid, and the anal excrement is also said to be infected, from this source man generally acquires the disease. The ova become infected and new generations of ticks can pass on the disease in hereditary fashion. Larval ticks are as capable of transmitting relapsing fever as adult ticks.

Pathology—In uncomplicated cases petechial hæmorrhages and occasionally jaundice are found. The spleen is soft and congested and often the site of multiple infarcts, while the liver is enlarged, friable and hyperæmic, and along with the kidneys and heart shows cloudy swelling and fatty degeneration. The long bones contain red marrow. Congestive changes in the cord and brain and iritis have also been described, especially with *T. duttoni*. Microscopically, spirochaetes are demonstrable in endothelial cells throughout the body, especially in the liver and spleen, and also in the brain and cerebrospinal fluid. Monkeys are susceptible and, as in the case of rats and mice, are actively immune after recovery. Krantz has applied the Reichenberg reaction or "adhesion test" to relapsing fever spirochaetes, specific immune serum causing the spirochaetes and blood platelets to adhere together.

Symptoms—A THE LICE BORNE RELAPSING FEVERS

1 *European form*—The incubation period varies from 2 to 12 days, and in accidental inoculations it is about 5 to 7 days. During this period slight prodromata may occur. The onset is sudden with a rigor, frontal headache and intense pains in the back and limbs. Anorexia, nausea and vomiting are common, and in children convulsions may occur, the temperature and pulse rise rapidly, the former often reaching 104° F. on the evening of the first day. The tongue is coated and moist, the spleen is enlarged and in some epidemics jaundice and a tender enlarged liver may be present. Herpes labialis may develop, and occasionally an erythematous rash appears at onset. Later, rose coloured spots may involve the skin of the neck, trunk and inner aspect of the thighs. Petechiæ are observed only in severe cases. After the fever has persisted for 5 to 7 days the temperature falls by crisis, accompanied by profuse sweating and possibly diarrhoea and collapse. The patient rapidly improves, but after an apyrexial period a relapse ensues, generally about the fourteenth day, followed by a second crisis about the end of the third week (twenty-first day). This usually terminates the illness, but occasionally a third relapse is noted. Spirochaetes are present in the blood until 24 hours before the crisis, when they rapidly disappear, and are not demonstrable except possibly in thick smears during the apyrexial period when a leucopenia replaces the characteristic febrile neutrophil leucocytosis. The blood remains infective between relapses, and if injected into a mouse or white rat spirochaetes appear in 24 hours.

2 *Asiatic relapsing fever* closely resembles the European form, but rigors are not so common, collapse is more frequent at the crisis, and relapses more numerous. Carter describes two varieties: (a) a short irregular remittent fever, (b) the so called bilious remittent or icteric fever. This is a severe form of infection associated with spirochaetal hepatitis. There is a high fever, intense toxic jaundice, skin petechiæ, splenomegaly, and an enlarged tender liver. The urine contains albumin, bile pigments, bile salts and urobilin. There is hyperbilirubinæmia associated with a direct biphasic van den Bergh reaction in the plasma. Toxic features are marked, and include a dry brown tongue, diarrhoea, abdominal distension, hiccough, stupor, delirium and coma. Death not infrequently results.

3 *North African relapsing fever* is found in Algiers, Tunis and Egypt, and closely resembles the European form. The number of relapses rarely exceeds three, but fatal cases may show jaundice, bilious vomiting, hepatomegaly, splenomegaly with infarctions, and albuminuria, necessitating differentiation from yellow fever.

4 *American relapsing fever* due to *T. novyi* has a low mortality rate and not generally more than one relapse.

B THE TICK-BORNE RELAPSING FEVERS.

1. *Central African relapsing fever*—**Synonyms**—Tick Fever, Tete Disease, Carapata Fever

This form is found throughout British and Portuguese East Africa, Nyasaland, Uganda and the Congo Free State

It differs from the European form in the shorter duration of the initial fever (3 days), the irregular incidence, greater number of relapses and the scantiness of spirochætes in the peripheral blood. The incubation period varies from 5 to 10 days, generally being about 1 week. The tick bites may be accompanied by local inflammatory changes and the prodromata include mental lethargy and sweating. The attack may start gradually with malaise, vomiting and slight temperature which gradually increases, or suddenly with dizziness, headache and generalised pains, the temperature rapidly reaching 104° F. After the pyrexia is established these symptoms may persist and, in addition, chilliness, pain over the spleen, bilious vomiting, bronchial catarrh, diarrhœa, enlargement of the spleen and liver, albuminuria and herpes may occur. Generally after 3 to 4 days the fever terminates by crisis with profuse sweating. The patient feels weak and tired, but slowly regains his appetite and strength until the next febrile paroxysm, which may occur after an interval of 3 to 8 days. Third and fourth relapses are frequent and as many as ten may occur, weakness and emaciation then being marked. In severe and fulminating cases epistaxis, hæmaturia and jaundice may be met with, also occasionally involvement of the central nervous system, with coma and death due to cerebral embolism caused by tangled masses of spirochætes. Cranial nerve pareses are described, and spirochætes may be present in the cerebrospinal fluid, which frequently shows increased pressure and lymphocytosis.

2 *Persian and North-West Indian relapsing fever* presents a primary fever of some 4 days' duration followed by short bouts of pyrexial recurrence, five or more relapses are not uncommon. Some epidemics are very mild, others more severe. Often the spleen is not palpable, and icterus is uncommon except in the more severe epidemics.

3 Spanish relapsing fever caused by *T. hispanicum* resembles the tick fever of Central Africa. The initial fever lasts about 4 days, and is associated with splenomegaly and neutrophil leucocytosis. Iritis and facial neuritis are not infrequent complications during relapses, which do not generally exceed four in number.

Complications and Sequelæ—Bronchial catarrh is not infrequent during the initial fever, and pneumonia and parotitis may also occur. In some epidemics hæmatemesis and hæmaturia have been noted; in others jaundice and hepatomegaly are not infrequent. Rupture of the enlarged spleen has been reported, also ophthalmia, adenitis, neuritis and diarrhœa. In tick-borne relapsing fever (*T. duttoni* and *T. sogdianum*), cranial nerve palsies are not uncommon. The most frequent is unilateral or bilateral facial paralysis, but ptosis of the eyelid, strabismus, deafness and trigeminal neuralgia are recorded. Ocular lesions include optic atrophy, iritis, iridocyclitis, retinal hæmorrhage and opacities in the vitreous. Meningismus associated with pathological changes in the cerebrospinal fluid (lymphocytosis, etc.) is quite common.

Diagnosis—Relapsing fever has to be distinguished from influenza, typhus, malaria and trypanosomiasis, and, if there is jaundice, from yellow fever and Weil's disease. This is done by finding the specific parasite in the blood.

Prognosis—The prognosis varies. With the European types the mortality rate is only 3 to 5 per cent, but with the Asiatic type it is much higher. Jaundice is an unfavourable development. African tick fever is not infrequently fatal, especially in the aged and debilitated, and Central American tick fevers resemble the Central African variety.

Treatment.—**PROPHYLACTIC.**—Avoidance of contact with lice and ticks is necessary if infection is to be prevented. Delousing of troops in war-time is important. With *O. moubata* the avoidance of native dung huts, especially at night-time, and of old camping sites, is essential. With *O. papillipes* in Syria and Palestine infection is mainly acquired when visiting caves; these should be avoided.

CURATIVE.—Arsphenamine (0.3 to 0.6 g.) and neoarsphenamine (0.6 to 0.9 g.) are specific in all types of louse-borne relapsing fever; generally not more than two injections are needed for cure. These should be given early during the pyrexial period and preferably when spirochaetes are demonstrable in the blood smears. In relapses the dose is repeated. In tick-borne relapsing fever these arsenicals are of doubtful value, and with *T. duttoni* in Central Africa and *T. sordianum* in Palestine and Syria they do not materially influence the course of the disease, or the relapse rate. Claims have been made that aurothioglucose (Solganol B.) is of value in those cases in which the central nervous system is affected. In the latter, lumbar puncture may be indicated to reduce intracranial pressure. If collapse occurs at the crisis, stimulants should be given.

Penicillin in big doses will terminate the attack but does not prevent relapse. Chlortetracycline 0.5 g. 6-hourly rapidly controls the attack, but may also be followed by relapse.

RAT-BITE FEVER

Synonyms.—Souoku; Sokoshio; Rat-bite Disease.

Definition.—A chronic relapsing type of fever following the bite of rats, and due to the *Spirillum minus* (Carter, 1887); it is characterised clinically by a return of the inflammation in the healed wound, lymphangitis, adenitis, rigors, fever and a macular or papular purplish rash.

Ætiology.—The disease is common in Japan, China and Bombay, and cases have been reported from France, Italy, Spain, Britain, East Africa, West Indies and Australia. Anyone bitten by an infected rat may acquire the disease. In man the spirochetes were found in the bitten tissues and in the lymph glands by Futaki; they are demonstrable with difficulty in the peripheral blood, appearing as thick, short forms (3 to 6 μ), which on cultivation increase in length (20) μ . About 3 per cent. of house rats in Japan are carriers, and after experimental inoculation spirilla are present in the blood for the first fortnight of infection.

Pathology.—In human cases, degenerative changes in the liver and kidneys have been reported, while animals show congestion and swelling of the lymph glands and spleen.

Symptoms.—After being bitten the wound heals in an ordinary manner, but in from 2 to 6 weeks pain and swelling appear at the site of the old bite and the scar breaks down. The lymphatics draining the area of the bite become inflamed, with enlargement of the corresponding glands, while an acute myositis is often present; a definite ulcer may now mark the site of the bite, with an angry inflammation spreading away from it, and small vesicles may break out around it. When this has continued for some time, general symptoms make their appearance; the temperature rises to 103° F. or over; there may be rigors, vomiting, nausea, severe headache, joint pains, diarrhoea and general malaise. A specific rash then usually appears as dusky-coloured, purplish-red spots or a coloured, patchy erythema over the limbs, trunk and face, which lasts for some time and slowly disappears. After remaining high for 3 to 8 days, the temperature drops, often by crisis, and the symptoms generally ameliorate. After a varying period of time the first relapse appears with a return of the former symptoms. Pyrexia then disappears, only to be followed by further relapses, which in some of the reported cases have continued for months or even years. Considerable

debility follows the attacks, and finally the patient may pass into a very poor state of health. A transient or permanent nephritis may result, and exophthalmos and paresis have been recorded in some cases. Ultimately the infection tends slowly to disappear.

Diagnosis.—The history of rat-bite, the local lesion associated with lymphangitis and adenitis, the specific rash and recurrent fever are typical. In some ways the disease resembles syphilis, but the Wassermann reaction is negative. Spirilla are difficult to demonstrate microscopically in the peripheral blood, and white rats or mice should be inoculated with human blood.

Prognosis.—With modern treatment this is quite good, but previously it was not so, many cases continuing with chronic symptoms for years. A mortality of 10 per cent. has been given by some authors.

Treatment.—Arsphenamine or some of its derivatives should be given, commencing with doses of 0.3 g. One to three injections at 3-day intervals are usually sufficient to abolish completely all the symptoms and bring about a permanent cure. Penicillin in large doses (up to 2,000,000 units over 1 day) is also effective.

It has recently been shown that rat-bite fever may also result from infection with *Streptobacillus moniliformis*. Arsenic is not active against this organism. Penicillin in large doses (2 or more million units) is effective. Chlortetracycline may be used as an alternative where penicillin resistance is suspected, in doses of 0.5 g. 6-hourly for 10 days.

N. HAMILTON FAIRLEY.

E. PROTOZOAN INFECTIONS

MALARIA

Synonyms.—Ague; Paludism; Remittent, Intermittent, Marsh or Jungle Fever.

Definition.—A protozoal disease of man caused by various species of *Plasmodium* which infect the red corpuscles after undergoing a schizogonous stage in fixed tissue cells (hepatic parenchyma cells) and give rise to periodic fever, splenomegaly and anaemia; transmission is by female anopheline mosquitoes, which bite from sunset to dawn.

HISTORICAL.—Malarial fevers were recognised by Hippocrates in the fifth century B.C. In the Middle Ages, people in Europe suffered severely from the ague, being saved from its ravages by cinchona bark, probably brought back from Peru by the Jesuits in the first half of the seventeenth century. This remedy also enabled Sydenham and other physicians to separate malaria from other fevers. Laveran (1880) discovered both the parasite and the phenomenon of ex-flagellation in shed blood, but differentiation into the three species was not made until later. Manson (1894) formulated the hypothesis of mosquito transmission, but he thought that man acquired the disease from infected mosquitoes via water and not by biting. McCallum (1897) recognised the fertilising function of the "flagellating body". Ross (1898) worked out the correct transmission and developmental cycle of bird malaria (Proteosoma) in culicine mosquitoes, and having previously observed the partially developed oöcysts of human malaria in dappled winged mosquitoes (anophelines) he predicted a human life cycle similar to that observed in bird malaria. Later in the same year, Grassi, Bignami and Bastianelli (1898) demonstrated the complete development of *P. falciparum* in *Anopheles maculipennis* and transmitted the disease to man by the bite of infected mosquitoes.

Ætiology.—Two distinct ecological problems are presented in malaria—the parasite and its environment on the one hand, and the anopheline mosquito and its environment on the other.

Malignant tertian (M.T.) or subtertian malaria greatly predominates in the tropics, and benign tertian (B.T.) in temperate zones, while in the subtropics both these forms and quartan malaria may occur. The last has a patchy distribution. Malaria is not found between latitudes approximately 60° north and 30° south because temperature considerations limit its extension. The critical temperature determining development in the mosquito is about 60° F., and this must be maintained sufficiently long to allow the sexual cycle to be completed. In Europe the disease disappears at about 3000 feet, and in India and Africa at 6000 feet. Seasonal prevalence, which is not marked near the Equator becomes so farther from it. Throughout South-East Europe the malaria season extends approximately from June to October.

All races contract malaria, but European and Chinese are regarded as being more susceptible than Negroes and certain aboriginal races. In endemic areas malaria is commonest in children, but as a result of repeated infections both children and adults gradually acquire a certain degree of immunity (premunure) or tolerance, which only persists as long as parasites persist. In avian and simian malaria this depends on a specific enhanced phagocytic function and hypertrophy of the reticulo-endothelium in the spleen, liver and other organs.

M.T. malaria is chiefly responsible for epidemics, the factors necessary being a sufficient number of (1) good gametocyte carriers, (2) efficient anopheline vectors and (3) non-immune individuals. In hyperendemic areas, good gametocyte carriers amongst the native population are largely confined to infants and young children. Adults and other children developing premunure as a result of repeated infection with the local strains of *P. falciparum* and *P. vivax* rarely become carriers. Newly arrived adults in such an area who have not previously been exposed develop overt attacks of malaria if infected, and become most effective carriers; they are the main source of carriers in epidemic malaria involving armies fighting in the tropics.

In war when large bodies of "unsalted" troops have had to fight in hyperendemic areas of malaria, such as tropical Africa and New Guinea, big epidemics have resulted in which a large proportion of the Forces involved have become rapidly infected. The initial breakdown was caused by *P. falciparum* in about 80 per cent. of cases, but after treatment such individuals, when they relapsed, were found to be infected with *P. vivax*. In civilian life the tropical aggregation of labour may lead to similar consequences. Regional epidemic malaria, of which the Punjab epidemic (1908) and the Ceylon epidemic (1934) are examples, is dependant on the development of a large number of non-immunes consequent on a sequence of healthy years, followed by undue exposure to anophelism. Flood or drought may be the factors leading to an increase in the local anopheline vector. Prolongation of the transmission period is an important factor—especially in North India, where epidemics occur every 8 or 9 years. In the affected areas practically all the infants die, many young children and old people succumb, and the adults are so ill that the life of the whole community is paralysed. In the Ceylon epidemic failure of the crops and the resulting famine further lowered individual resistance, and within 7 months some 80,000

Asexual cycle in man (endogenous cycle; schizogony). The sporozoites, after inoculation by the mosquito, disappear within 2 hours from the blood which completely loses its infectivity—even when 200 ml. are injected intravenously into a susceptible individual. On the seventh day in *P. falciparum* infection and on the ninth day in *P. vivax* infection the blood regains its infectivity as shown by positive sub-inoculation results, and 2 or 3 days later intracorporeal parasites become demonstrable in blood smears. During the period of non-infectivity the sporozoites leave the blood-stream and enter fixed tissue cells, especially the parenchyma cells of the liver, where they undergo an exo-erythrocytic schizogonous cycle before discharging the first generation of merozoites into the blood-stream. Large nests of these non-pigmented pre-exo-erythrocytic parasites have recently been demonstrated in the liver on the seventh day following experimental hyperinfection of a human volunteer with *P. vivax* by Shortt and his colleagues. Though late tissue forms have not yet been found in benign tertian infection in man, both pre-erythrocytic and late exo-erythrocytic forms have recently been discovered in the liver of monkeys infected with *P. cynomolgi* (Shortt and Garnham).

The pre-erythrocytic parasites in malignant tertian malaria have recently been demonstrated. Subinoculation experiments on human volunteers indicate that this tissue phase lasts only a few days and that once merozoites have been produced, there is every reason to assume exo-erythrocytic forms do not persist in infections with *P. falciparum* as they do in *P. vivax*.

The asexual growing forms (trophozoites) at first have their cytoplasm arranged somewhat crescentically around a central vacuole and contain one or more small masses of chromatin. With increase in the size of the vacuoles definite ring forms result. As the parasite enlarges malaria pigment appears, and medium-sized amœboid-like forms are produced. As the parasite reaches maturity pigment collects centrally and the chromatin divides into two, four or more portions each surrounded by a mass of cytoplasm; this is known as the sporulating, segmenting or rosette form or the schizont. The mature schizont consists of a variable number of young forms (generally 8 to 16), known as merozoites, which soon escape into the plasma and subsequently invade fresh red cells restarting the cycle.

Sexual cycle in the mosquito (exogenous cycle; sporogony). In addition to these asexual forms produced during schizogony in man, certain sexual forms (gametocytes) are liable to appear in the blood following a bout of malaria fever. These are large round or oval bodies filling and expanding the erythrocytes in benign tertian infections, and crescent-like bodies in malignant tertian malaria; when these crescents are imbibed by suitable anophelines the corpuscles are ruptured and they revert to a circular form in the mosquito's stomach. Here the male gametocytes produce flagella (microgametes), which separate off (exflagellation) and subsequently penetrate the female gametes (macrogametes) produced by maturation from macrogametocytes. The resulting body, known as the zygote, develops into the elongated travelling vermicle or ookinete which penetrates the stomach wall: here it becomes circular in outline and develops into an oöcyst which finally becomes packed with sickle-shaped sporozoites causing a cyst-like protrusion on its outer surface. These oöcysts subsequently rupture and sporozoites escape into the body cavity (bæmocele) and ultimately make their way to the salivary gland. When the mosquito bites, the sporozoites pass with the salivary secretion into the new host (see Asexual Cycle in Man). The time taken to complete this cycle varies from 8 to 20 days, temperature conditions being an important factor in rate of development.

Mosquito vectors of malaria.—It is not every anopheline mosquito which can transmit malaria successfully. Perhaps the best-known transmitter of malaria is *A. maculipennis*, which is nocturnal in habit, and has been specially studied in Europe and the Eastern Mediterranean. Hackett, Missiroli and others have shown that *A. maculipennis* is not a uniform species, but is divided into "biological races" or

varieties. These races cannot generally be distinguished either as adult or larvæ, but only by their egg characteristics. The breeding grounds, sexual behaviour and feeding habits differ. Thus, the race called *elutus* bites man for choice, and is a dangerous carrier of malaria; other races, like *typicus* and *messeeæ*, bite cattle for choice, and therefore are much less dangerous to man. The larvæ of *elutus* need traces of salt in water, and for this reason they tend to have a coastal distribution. In the Balkans, malaria of the plains is mainly transmitted by *A. maculipennis* var. *elutus*, whereas malaria of the hills is solely transmitted by *A. superpictus*, which especially breeds in running mountain streams with rough rocky beds. It follows that the mosquito vector should be carefully studied in every country and special local methods devised for its extermination. Drainage of swamps, land reclamation, elimination of breeding sites and destruction of larvæ by D.D.T., oiling, etc., are essential factors in malaria control.

There are many different vectors in other parts of the world, some of the more important of which are: *A. albimanus*, tropical America; *A. quadrimaculatus*, United States; *A. funestus*, tropical Africa and India; *A. gambiae* (costalis), tropical Africa, Arabia and Brazil; *A. culicifacies*, India and Ceylon; *A. stephensi*, breeding in wells in cities in India; *A. maculatus*, India, South-East Asia and Netherlands East Indies; *A. minimus*, India, Burma, etc.; *A. sundanicus* (ludlowi), the dangerous brackish-water breeder in the Far East; *A. punctulatus* var. *typicus* and *A. punctulatus* var. *moluccensis*, New Guinea and New Britain.

The danger of the introduction of new anopheline vectors into other countries is illustrated by that most dangerous African vector, *A. gambiae*. This species reached Brazil, probably by aeroplane or destroyers, in 1930, and was followed by severe outbreaks of malaria, the epidemic in 1938 causing 50,000 cases. More recently *A. gambiae* appeared in the Nile Valley in Egypt, where the usual vector is *A. pharauti*.

Parasites in blood smears.—All forms of *P. vivax*, *P. malariae* and *P. ovale* are met with in the peripheral blood, but in malignant tertian malaria owing to sporulation in the internal organs, generally only the small rings and large crescents of *P. falciparum* appear. Blood smears are stained by Leishman's or Giemsa's stain, while Field's rapid staining method gives excellent results in thick films in routine diagnosis. The following points assist in differentiating the different species. **Ring forms.** The rings of *P. falciparum* occupy about one-sixth of the cell, which may show Maurer's clefts. They are often fine and hair-like, and show irregular or flattened marginal forms. Two chromatin dots and multiple infection of the same corpuscle may occur; occasionally this is seen with *P. vivax*. The rings of *P. vivax* and *P. malariae* occupy about one-third of the cell, are larger and contain more cytoplasm, but the species cannot always be determined if only ring forms are present (Wenyon). **Partly grown forms.** In *P. vivax* the infected corpuscle is enlarged, Schüffner's dots are present, and the parasites are of irregular shape and contain light-brown pigment. With *P. malariae* there is no enlargement of the corpuscle, the pigment is dark brown or black, band forms are common, and Ziemann's stippling may be demonstrated in the red cells by special staining. **Adult forms.** In *P. vivax* and *P. malariae* the schizonts have 16 and 8 merozoites respectively, in contrast with which the gametocytes have a single nucleus and a different distribution of pigment and chromatin. *P. ovale* somewhat resembles *P. malariae* morphologically, but infected corpuscles show Schüffner's dots, and are often oval or distorted in shape with serrated edges.

Pathology.—Clinical—In severe and persistent infections there is considerable blood destruction. The intra-corpuscular parasite digests hæmoglobin, depositing the hæm moiety as malaria pigment (hæmatin). Though free hæmoglobin is not generally detected spectroscopically in plasma collected during or after the paroxysm, Schumm's test for methæmalbumin is often positive if the fever be prolonged, indicating that corpuscular lysis with liberation of extracorporeal hæmoglobin is occurring. Hæmatogenous bilirubin also tends to be increased, the indirect van den

Bergh reaction varying from 10 to 80 units. Hyperbilirubinæmia is responsible for the hæmolytic icterus and pleocholia observed in severe and persisting infections.

In untreated infections, especially M.T., severe anæmia may rapidly develop. Before the disease has become chronic, anæmia in uncomplicated cases is generally normocytic in type. The blood picture may show polychromasia, anisocytosis, poikilocytosis, punctate basophils, and occasionally normoblasts. Hypochromia may develop later. Leucopenia with a left shift and a decrease in both lymphocytes and polymorphonuclear neutrophils occur early in the infection and are a characteristic finding.

The urine may be dark brown in colour due to urobilin. Albuminuria is not uncommon, and casts and other evidences of nephritis may be found in quartan malaria. Bile pigments and bile salts generally indicate malaria hepatitis. Delayed excretion of bromsulphthalein and other tests for liver function may indicate liver damage.

Morbid anatomy—In a fatal case of *acute pernicious malaria* the spleen is enlarged and congested, blackish red in colour, with soft, dark pulp. The liver is also congested and enlarged, while the gall-bladder is distended with brownish-black bile. Small hæmorrhages may be present in both these organs. The serous membranes and mucosa of the gastro-intestinal tract are congested and leaden-coloured and may show small hæmorrhages. Lipoid and fat may disappear from the cortical layer of the suprarenals. The heart muscle is often pale and flabby, showing cloudy swelling or actual fatty degeneration, ecchymoses on the myocardium and pericardium are not infrequent. The marrow of the short bones is dark or chocolate coloured, while that in the long bones presents a variable picture depending on the degree of hyperplasia. In cerebral malaria the meninges are hyperæmic, the cortex is a smoky or leaden-grey colour, while punctiform hæmorrhages are scattered through the white matter.

The *microscopic* study of the organs in fatal cases has done much to explain the varied clinical manifestations of the disease. Thus:

(1) Pigmentation of the serous membranes and internal organs is caused by malaria pigment (hæmatin) contained in parasitised red cells in the capillaries, in macrophages, and R.E. cells, particularly in the red pulp of the spleen or the sinusoids of the liver and bone marrow. A fine, yellow granular pigment, hæmosiderin, giving the Prussian-blue reaction for iron with ferro-cyanide, is also found in the parenchyme cells of the liver, spleen and kidneys. (2) The early enlargement of the liver is mainly due to acute congestion, and in the case of the spleen to congestion and commencing hyperplasia of R.E. cells of the red pulp, some of which may show toxic degeneration. (3) Degenerative changes, due to toxic action or anoxia or both, are manifested in the polygonal hepatic cells, the convoluted tubules of the kidney, the cortical cells of suprarenal glands, and capillary endothelium giving rise to multiple hæmorrhages. (4) Capillary blockage by parasitised corpuscles and possibly vascular spasm lead to local tissue anoxia and possibly vascular spasm with small areas of hæmorrhage and necrosis possibly followed by neuroglial proliferation and the formation of so called "malaria granulomata". Proliferative changes of the reticulo-endothelium in the capillary areas of the brain leading to granulomata are also described. In *chronic malaria* in which repeated infection has occurred for years the spleen ("ague cake") is very enlarged and hard, the capsule is thickened, and often adhesions bind it firmly to the diaphragm, etc., sometimes the adhesions are calcified. Microscopic section shows great hypertrophy of the R.E. cells, which often contain malaria pigment, atrophy of the Malpighian bodies and lymphoid tissue generally and extensive fibrosis.

Symptoms—The natural history of malaria in the untreated or ineffectively treated patient includes (i) an incubation period during the later stages of which mild premonitory symptoms may appear, (ii) a stage of primary fever which if the patient

survives is followed by (iii) a period of latency in which demonstrable parasites are generally absent but in which subinoculations of blood may be positive, (iv) a stage of recrudescence, relapse or recurrence.

(i) INCUBATION PERIOD

In experimentally infected volunteers the average incubation period is 10 days in M.T. and 12 days in B.T. malaria, but variations occur and in natural infections the period may vary from 8 to 23 days. In quartan malaria it is often longer. Occasionally in B.T. infection the primary fever may be suppressed and the incubation period extended to as long as 9 months; this may also happen in individuals taking suppressive antimalaria drugs at the time of infection.

Premonitory symptoms.—When thick films are carefully examined the average time for parasites to be found microscopically in experimentally infected volunteers is 9½ days with *P. falciparum* and 12 days with *P. vivax*. For some 3 days previously, however, in heavy infections minor clinical features such as transient headache, backache and generalised aches and pains may be experienced while tenderness of the liver and slight rises of temperature (99° F.) are not uncommon. Though microscopical examination at this early stage generally reveals no parasites, subinoculations of the blood invariably prove positive on the seventh day in M.T. and on the ninth day in B.T. malaria; certain characteristic haematological changes also begin to appear, namely, a decrease in lymphocytes and segmented polymorphonuclear leucocytes leading to a leucopenia and later a left polymorphonuclear shift due to an increase in the non-segmented leucocytes. These premonitory minor features may also appear after exposure to heavy infection in volunteers who are taking schizonticidal drugs like mepacrine regularly, as well as in those who are receiving no antimalarial suppressive drug; in the latter, however, these features are not transient, but increase in intensity until an overt attack of malaria with major symptoms and demonstrable parasites supervenes. In natural infections which are generally lighter than in experimentally infected volunteers these premonitory symptoms are less frequently encountered.

(ii) PRIMARY FEVER

At the onset of primary fever, parasites are often very scanty and may only be found after prolonged search. The onset of fever is undoubtedly related to segmentation, but it is not dependent exclusively on parasite density; while some pyrogenic substance may be directly responsible, variable host reaction is an important factor. There is often an initial period of continuous, remittent or intermittent fever which lasts a variable period. Intermittent fever generally becomes established at an earlier stage in B.T. than in M.T. primary fever, and though the temperature may be quotidian at first it later becomes tertian in type. Occasionally, the primary B.T. fever may be tertian at onset and quotidian later. Untreated B.T. patients may have intermittent fever every day for many weeks before spontaneous remission occurs, and a tertian periodicity may only be established in recrudescences or relapses. In quartan malaria, which particularly affects children, a quartan periodicity tends to be established early, even in primary fever, and in untreated individuals typical paroxysms of ague may persist for many months before the latent phase becomes established. If there are interpolated attacks due to multiple strains, a double or triple quartan chart may ensue; the last is associated with quotidian fever.

In the ordinary septuaxenic type, the onset is either sudden or insidious, with prodromal symptoms, such as tiredness, stiffness of the neck muscles, pains in the muscles and bones and anorexia. Fever, when it appears, is generally associated with headache, backache, aching pains in the bones, malaise and fatigue. Shivering

is often absent, especially in M T infections, while nausea, anorexia and vomiting are common

The spleen though always increased in size is frequently not palpable in the early stages of the disease, later, it is felt as a tender soft mass below the left costal margin, moving on respiration. Splenic pain may be troublesome. The liver is often demonstrably enlarged earlier than the spleen in primary malaria, it is frequently tender and its edge may be palpated below the right costal margin moving with respiration. The gall bladder may also be distended later, though this is rarely demonstrable. Herpes on the lips and face is common and should suggest the possibility of malaria. Mild bronchitis is another suggestive sign, while abdominal pain, constipation or diarrhoea are not infrequent. If treatment be delayed signs of blood destruction develop, they include (1) anæmia (2) hæmolytic jaundice, (3) polycholia with bilious vomiting and chocolate coloured stools and (4) brown urine due to urobilinuria.

Prior to the spleen becoming palpable, influenza, dengue, sand-fly fever, scrub typhus or enterica may be suspected. After the spleen is demonstrably enlarged diseases associated with splenomegaly, such as typhoid, paratyphoid, undulant fever, relapsing fever, kala azar and trypanosomiasis need differentiation. Amœbic abscess, cholecystitis, pyelitis, subacute bacterial endocarditis or occult sepsis may simulate malaria. In bacterial infections there is often a polymorphonuclear leucocytosis and the febrile attack comes on later in the afternoon or evening than is customary in malaria. When jaundice complicates the picture infectious hepatitis, yellow fever and leptospirosis may need differentiation. So called typho malaria may occasionally develop. Here the temperature chart, splenomegaly, hæmorrhage from the bowel or epistaxis and the development of the so-called "typhoid state" with low muttering delirium may suggest typhoid until parasites are found in the blood. Blood cultures should invariably be made to exclude enterica in such cases, as malaria and typhoid may occur together.

Bilious remittent fever is a well recognised type, characterised by remittent fever, epigastric discomfort, bilious vomiting, chocolate coloured stools and urobilinuria. The spleen and liver are both enlarged and tender, and the skin and scleræ show icterus. The jaundice may be caused by excessive blood destruction or by toxic degeneration of hepatic cells, in the latter case bile pigment and/or bile salts appear in the urine. Bilious remittent fever may be a manifestation of primary or recrudescent M T infection.

Acute pernicious malaria—Apart from the general septicæmic features induced by parasæmia, and the anæmia and jaundice resulting from blood destruction, there are a number of manifestations classified as acute pernicious malaria, which are mainly dependent on internal sporulation and localised blockage of the capillaries by *P. falciparum* in different organs, such as the brain, heart, intestines and spleen by parasitised corpuscles, which adhere to one another and to the capillary endothelium. This phenomenon is peculiar to *P. falciparum* infections, and is chiefly responsible for the diverse symptomatology of M T malaria. Its onset may be suspected if hyperinfection be present. Hyperinfection is diagnosed if more than 5 per cent of erythrocytes are infected, if more than 5 per cent of infected corpuscles contain 2 or more parasites and if pigmented asexual forms of *P. falciparum* are demonstrable in blood films. In extreme cases, 30 per cent. of the corpuscles may show parasites. The chief forms of acute pernicious malaria are as follows:

1 *Cerebral*—Such patients may develop coma, convulsions, paraplegia, hemiplegia, aphasia, meningismus or hyperpyrexia. Cerebrospinal fever may be suspected, or the condition be diagnosed as primary heat stroke. The coma may come on rapidly, or be preceded by drowsiness and stupor. In some instances there is great excitability and maniacal and suicidal tendencies may develop, alcoholism or lunacy may be diagnosed with disastrous results. Generally the face is suffused, the

pupils contracted and the reflexes modified, increased deep reflexes and extensor plantar responses are common. Malaria coma has to be distinguished from cerebral and pontine hæmorrhage, uræmia, diabetic coma and alcoholic or opium poisoning. The blood always contains parasites. Lumbar puncture shows a clear fluid perhaps under increased pressure, a pleocytosis may be found, especially if meningitic symptoms are present.

2 *Algid*—The patient presents the picture of severe shock and peripheral circulation on failure. There is a Hippocratic facies, the skin is cold and covered with clammy sweat, the respirations shallow, the pulse rapid, thready and weak and the blood pressure very low. Vomiting, diarrhoea and epigastric pain are not uncommon. Though the skin temperature is low the internal temperature is often high. Parasites are plentiful in the peripheral blood smears.

3 *Cardiac*—There is breathlessness, cyanosis, congestive failure and sometimes sudden death. Degenerative myocardial changes and blocked capillaries are the basis of the syndrome.

4 *Gastro intestinal*—In gastric malaria there is epigastric discomfort and tenderness severe bilious vomiting and occasionally hæmatemesis. Gastric ulcer may be diagnosed. In the small intestinal type cholera may be simulated but the fluid stools are brown, not colourless. Where the large bowel is involved the stools may contain blood with or without clear mucus, the mucus, however, does not contain cellular exudate, and sigmoidoscopy fails to show ulceration though congestion and small mucosal hæmorrhages may be observed. Occasionally large hæmorrhages occur. Bacillary dysentery or intussusception may be erroneously diagnosed.

5 *Abdominal*—Abdominal discomfort and pain are not infrequent in primary M T malaria. If associated with vomiting and tenderness over the liver, gall bladder, epigastrium or cæcum, an erroneous diagnosis of cholecystitis, gastric ulcer, pancreatitis or appendicitis may be made. In malarious areas a careful blood examination should invariably precede any abdominal operation, only by so doing can serious mistakes be avoided.

6 *Purpuric*—Petechial or purpuric skin eruptions, epistaxis, hæmatemesis, hæmoptysis, melæna, hæmaturia or vaginal hæmorrhages are occasionally encountered.

7 *Renal*—Albuminuria is common, and in severe infections may be associated with renal casts and red blood cells in the urine.

It is to be noted that acute pernicious malaria may also occur in M T recrudescences as well as in primary fever. If the patient survives the primary attack and has not been cured, a period of latency supervenes.

(iii) PERIOD OF LATENCY

Fever and clinical symptoms are absent though enlargement of the spleen may be found. Though parasites cannot be demonstrated even in thick films malaria fever results in M T infection when blood is subinoculated into a susceptible individual, but subinoculations are frequently negative in B T infections. All available evidence indicates that this is due to the persistence of secondary exo erythrocytic forms in B T which are absent in M T malaria. Persons with latent M T malaria are always unsuitable donors for blood transfusion, while those with latent B T infection occasionally transmit malaria to the recipients. If the latently infected individual be injected with blood containing his own strain of parasites malaria fever and parasites fail to develop (premunition, premunity), but if he be injected with another strain of the same species or with another species of *Plasmodium* a typical attack of malaria results. This specificity is probably dependant on specific opsonins which prepare parasitised cells for phagocytosis by hypertrophied R E cells and macrophages. This phase of latency—especially in B T and quartan malaria—may

last from many weeks to many months before fever reappears. Certain factors such as chd, wetting, exposure, exhaustion, blood loss, anæsthetics, surgical trauma and high-altitude flying (anoxia), may upset the biological balance between host and the parasites and induce recrudescence or relapse.

(iv) RECRUDESCENCES AND RELAPSES

This stage is characterised by periodic intermittent fever and typical ague attacks with cold, hot and sweating stages. In M.T. and B.T. malaria pyrexia occurs on alternate days, in quartan fever every fourth day. Onset of fever is generally in the morning or early afternoon.

In M.T. malaria, pyrexia generally recurs in from 1 to 6 weeks, and under these circumstances is classified as a recrudescence rather than a relapse. The fever, which at onset may be quotidian in type, soon establishes tertian periodicity. The temperature rises less abruptly and is generally lower than in B.T. ague, and chilliness rather than a rigor is characteristic. The hot stage tends to be more prolonged and the sweating stages less intense, while paroxysms last longer, *i.e.* 12 to 24 hours. Fatigue, backache, headache, pains in the limbs, anorexia, nausea and vomiting, which may be bilious in type, are common. If the fever is uncontrolled by treatment the spleen becomes rapidly enlarged and tender, and hepatomegaly, hæmolytic anæmia and perhaps jaundice develop. Unless the individual has been taking an antimalarial drug for suppressive purposes, parasites are readily demonstrated in recrudescences even at the beginning of fever; as in primary fever hyperinfection and acute pernicious manifestations may develop with fatal results. Unless cured, liability to relapse persists for about 6 months.

In B.T. malaria, a longer period generally intervenes between primary fever and secondary attacks, *i.e.* relapses rather than recrudescences are the rule. With some strains of *P. vivax*, however, secondary attacks supervene some 4 to 6 weeks after the primary fever. They are characterised by typical attacks of tertian ague similar to those in the primary attack.

Cold stage.—The patient feels listless and develops headache, backache, pains in the limbs and chilliness. Then the rigor begins. He lies curled up in bed with chattering teeth, shivering violently. The face is pinched and the skin cold and blue. Blankets and rugs are applied in an effort to keep warm. Nausea and vomiting are not uncommon. After $\frac{1}{2}$ to 2 hours the axillary temperature rises rapidly, attaining a height of 103° to 106° F.

Hot stage.—The skin becomes burning hot and bedclothes are discarded. Fever is now high, the face is flushed, the pulse is rapid, the carotids throb and the head aches. In severe cases delirium may develop. This stage persists for 8 to 10 hours.

Sweating stage.—The skin now moistens, profuse sweating ensues, pains and headaches disappear, the pulse slows, the tongue becomes moist, the temperature falls, slowly at first and then more rapidly, until a normal or subnormal level is reached. At the end of the attack the patient feels reasonably well.

Splenomegaly, anæmia and herpes are characteristic of recurrences, especially if fever is not early controlled by treatment. Usually relapses tend to get milder, with progressively longer intervals between. Liability to relapse may persist for 2 to 3 years.

In Quartan malaria relapses, the paroxysm is often shorter than in B.T. ague (6 to 8 hours), and the temperature tends to be higher, temperatures of 105° to 106° F. are common. Spontaneous recoveries are few, and long periods of latency occur between relapses. Infections may persist for 7 years or longer, while solid premunity is rarely established.

Malaria cachexia—In old-standing cases, especially if there are repeated infections with different strains and species of parasite and inadequate treatment, the spleen

becomes stony hard and very enlarged, and perisplenitis may give rise to severe splenic pain and discomfort. Cachexia, anaemia, a dirty earthy-coloured skin, digestive disturbances, enlargement of the liver, physical inertia, oedema of the feet and ankles, deterioration of memory and lack of concentration may develop. There may be long intervals of apyrexia or subnormal temperature, but transient bouts of fever may occur in which parasites are demonstrable in the blood for a short time only.

The clinical picture at this stage is often complicated by the effects of dietary deficiency. Thus, (1) haemolytic macrocytic anaemia may follow lack of good biological protein and possibly vitamin B complex as in Macedonia, (2) microcytic hypochromic anaemia occurs if there is lack of iron in the diet, as in parts of India, ankylostomiasis here may also be a complicatory factor, and (3) neuritic manifestations may follow deficiency in B₁.

Complications and Sequelæ—Complications include herpes of the lips, nose, eyelids and cornea, supraorbital neuralgia, anaemia, malaria hepatitis, pigment gall stones, nephritis, with or without oedema and ascites (especially encountered in quartan infections in childhood), abortion and premature birth. Ocular complications include conjunctival haemorrhage, corneal ulceration, keratitis, iritis, choroiditis, retinal haemorrhages, optic neuritis and malaria amblyopia. Dendritic corneal ulcers are the most common ocular complication, the lesions being generally superficial seldom penetrating into the deeper corneal layers. The mild lesions clear up in 2 to 4 weeks the more severe taking months to heal. They frequently develop from herpetic lesions but may also arise without previous corneal involvement. Malarial amblyopia may follow cerebral malaria, the disks are a cherry pink colour with blurred edges in contrast to the pale or white disks observed in quinine amblyopia. Retinal haemorrhages may also follow cerebral malaria, but they are most commonly associated with severe anaemia. Agranulocytosis and purpuric manifestations with petechial haemorrhages into the skin occasionally develop.

Splenic complications include (1) perisplenitis, (2) subcapsular haematoma, (3) rupture and (4) torsion of the pedicle. Rupture of the spleen is an important complication which may occur in either acute or chronic malaria. It may occur spontaneously or follow trauma or such acts as sneezing or straining at stool. The onset may be sudden or gradual, in the latter case a small tear may lead to a subcapsular haematoma which may rupture later. Tears generally occur on the visceral side close to the hilum. A subcapsular haemorrhage may be associated with severe splenic pain, and if a subcapsular haematoma impinges on the diaphragm it may produce (1) left shoulder pain, (2) splinting or elevation of the left diaphragmatic leaf and (3) evidence of collapse or consolidation involving the lower lobe of the left lung. When rupture occurs through the capsule into the peritoneal cavity there is local evidence of splenic and peritoneal involvement combined with symptoms of internal haemorrhage. In cases with chronic malarial splenomegaly ('ague cake spleen'), dislocation of the spleen or torsion of its pedicle may occur. Both rupture of the spleen and twisting of the pedicle necessitate immediate operation, but subcapsular haemorrhage may be treated conservatively by medical means.

The most important sequela of malaria amongst Europeans in the tropics is black water fever, which is described separately.

Certain mental conditions, including psychoses, aphasia, sexual impotence and loss of memory, have been described as sequelæ of long continued malaria. Many of these are undoubtedly functional in origin and associated with the mental stresses or strains of life in the tropics.

Diagnosis—Malaria is an arch simulator, and in acute pernicious malaria or primary fever before periodicity has become established, and splenomegaly and anaemia have developed, a certain diagnosis can only be made by demonstrating parasites. Owing to the absence or scarcity of demonstrable parasites in the early stages thick as well as thin blood films should be examined, and several examinations should

that M T and B T parasites appear in the blood at the usual time, but that if the drug is present in adequate concentrations, the asexual parasites are destroyed, neither drug has any action on pre-erythrocytic parasites (Fairley). Other chloroquine salts are obtainable, such as the sulphate (Nivaquine). The adult dosage is the same, i.e., 2 tablets once weekly.

Proguanil (Paludrine) is probably the best suppressive drug; in non-toxic dosage it is a true causal prophylactic in M T malaria. It inhibits the production of asexual parasites from pre-erythrocytic forms in B T. infections while the drug is being taken (partial causal prophylactic) and in addition it has a schizonticidal action on asexual parasites. Its administration need not be commenced until 24 hours before arrival in a malarious area. The dosage advised each day is 100 mg for adults, 50 mg for children of 6 to 12 years of age and 25 mg for those under 5 years and infants. Daily administration is recommended for non-immunes, not because it is essential, but because it is more readily remembered. Experimental evidence indicates that 1 tablet (100 mg) if invariably taken once every 3 days would suffice to prevent falciparum infections and effectively suppress vivax infections. Alternatively, a single dose of 0.3 g may be given on the same day once a week, but owing to the long interval between successive doses not all pre-erythrocytic forms will be destroyed by this regimen and asexual parasites will sometimes gain access to the blood. Under these circumstances subsequent suppression and cure will depend on the schizonticidal action of proguanil. This weekly regimen is particularly useful in native labour groups with some degree of premunity and where its regular administration can be supervised.

It has been shown recently that drug resistance may appear in certain areas. Where this is suspected proguanil should be stopped and mepacrine or chloroquine substituted.

Pyrimethamine (Daraprim) has been shown to have an action similar to that of proguanil. It may be given in doses of 25 mg (1 tablet) once weekly in adults and half this dose in children of 6 to 12 years. Unfortunately, cross-resistance has been shown between this drug and proguanil, so that where proguanil resistance is suspected, pyrimethamine should be withdrawn and mepacrine or chloroquine substituted.

CURATIVE—The best known antimalarial drugs are quinine, mepacrine, pamaquin, chloroquine and proguanil. Arsenic compounds have distinct therapeutic action on the schizonts and gametocytes of *P. vivax*. Not all strains of malaria parasites of a given species, necessarily respond therapeutically to the same dosage of a given antimalarial drug, and for this reason the optimum dosage and the particular course of treatment may need to be varied within limits in different geographical areas. Antimalarial drugs in tablet form are best administered with a copious draught of water after food.

Quinine—This is a crystallisable alkaloid obtained from cinchona bark, chemically it is a quinoline compound of complex molecular structure which has recently been synthesised. Various salts are available, the insoluble sulphate and the soluble bisulphate being mainly used. Quinine exerts schizonticidal action on all human species of plasmodia, and is gametocidal for all except *P. falciparum*. Regarding dosage, opinions differ, but in primary malaria if quinine is used alone it is sound therapy to give gr 30 of the bisulphate for 10 days and gr 20 for the next 10 days. The drug is best given in a mixture in $\frac{1}{2}$ oz doses as follows: Quinine sulph gr 10, Acid sulph dil m 10, Syr simplex dr 1, Aq chlorof ad oz $\frac{1}{2}$. If vomited, the dosage should be repeated. Children bear quinine well, the dosage being appropriate to age. Toxic effects such as tinnitus, deafness, gastric and visual disturbances including amblyopia may develop. Idiosyncrasy may result in severe erythematous and urticarial rashes. The administration of quinine even in therapeutic dosage does not precipitate blackwater fever in recent malaria infections, there is general agreement, however, that there is some relationship between its administration and the

onset of blackwater fever in patients suffering from chronic recurrent or latent malignant tertian infections, especially where they have been irregular quinine takers. For this reason and also because they are more potent schizonticides, mepacrine or chloroquine possess certain advantages for therapeutic use.

Mepacrine (Atebrin, quinacrine)—Mepacrine hydrochloride is a synthetic acridine derivative which compares very favourably with quinine, it is a good schizonticidal drug and destroys the gametocytes of *P. vivax* and *P. malariae*, but not of *P. falciparum*. The following course is suitable for the treatment of non immune adults. During the first 24 hours an initial dose of 0.2 g. of mepacrine should be given, followed by 0.2 g. at 6 hourly intervals (total = 0.8 g.). On the second day 0.2 g. is given thrice daily, and for the next 4 days the dosage is 0.1 g. thrice daily (total course = 2.6 g.). A maintenance dose of 1 tablet (0.1 g.) daily should be taken for 1 month to ensure radical cure. Mild gastro intestinal symptoms including nausea, abdominal discomfort and vomiting may occasionally occur, but real idiosyncrasy is very rare. Harmless and transient yellow staining of the skin may follow. With this dosage, toxic nervous features are not observed in healthy adults but if it be increased to a total of 2.0 g. in the first 48 hours occasionally toxic psychoses or transient convulsions may result. In individuals who are taking mepacrine (0.1 g. daily) for suppressive purposes over long periods, a lichen planus like eruption occasionally develops, once this happens the drug should not be given again.

Pamaquin (plasmoquin)—This is an 8 amino quinoline derivative synthesised by Schuleman, and which can destroy M.T. gametocytes but has practically no effect on the schizonts of *P. falciparum*, in B.T. and quartan infections it exerts lethal effects on both schizonts and gametocytes and in many cases on the EE forms. As a gametocide, 1 tablet of pamaquin naphthoate that is, 23 mg. of the salt (i.e. 10 mg. of base) or 18 mg. of the salt (i.e. 8 mg. of base), is very effective when given thrice daily for 3 days. Pamaquin is also very valuable when used in conjunction with quinine, proguanil or chloroquine in producing radical cure of B.T. malaria.

Dosage regimes are Quinine gr. 10 pamaquin 8 to 10 mg. base given three times a day concurrently. Proguanil 100 mg. may be substituted for quinine. The treatment is continued for 10 days during which the patient should be kept in bed and encouraged to drink plenty of fluid.

Headache colicky abdominal pain and cyanosis due to methæmoglobincythæmia may follow pamaquin administration. Pamaquin hæmoglobinuria is a rare complication which has to be differentiated from blackwater fever in which no methæmoglobin is found within the corpuscles.

Other 8 amino quinolines recently introduced are pentaquine, iso pentaquine and primaquine. The action and dosage of these drugs are similar to those of pamaquin. Primaquine is regarded as the most active and least toxic, and is given in doses of 15 mg. daily together with a schizonticide as above.

Mepacrine should not be used in conjunction with the 8 amino quinolines.

Chloroquine diphosphate (Aralen)—This is a 4-amino quinoline compound which is colourless and does not discolour the skin. It is rapidly and almost completely absorbed, produces a high blood concentration, is stored in the internal organs such as the liver, spleen and kidneys and is excreted slowly—at about the rate of 60 per cent. per week after drug administration ceases. It has a similar antimalarial action to mepacrine, being an excellent schizonticide and a good suppressant, it exerts no causal prophylactic effect in M.T. or B.T. malaria, nor has it any direct action on M.T. gametocytes.

It produces rapid clinical cure and often radical cure in M.T. malaria and effectively controls the acute febrile attack in B.T. infections but does not prevent vivax relapses. For treatment of overt attacks a total course of 2.5 g. is advised, 6 tablets on the first day and 2 tablets on the second and third days. Each tablet of Aralen contains 0.25 g. of chloroquine diphosphate (= 0.15 g. of base). Toxic symptoms

include mild and transient headache, visual disturbances such as blurred vision and difficulty in focusing, pruritus and gastro intestinal complaints. As with mepacrine lichen planus like lesions occasionally supervene after prolonged administration for suppressive purposes. Other 4-amino quinolines such as camoquin are also successful. The sulphate of chloroquine (Nivaquine) is now commonly used. Tablets contain 0.15 g of the base and are given in the same dosage as the diphosphate.

Proguanil (Paludrine hydrochloride)—This is a biguanide, discovered by Curd, Davey and Rose in 1944, which has a wide range of action on different phases of the malaria parasite. It is rapidly and almost completely absorbed reaching a peak concentration in about 3 hours. Excretion of the drug is more rapid than with mepacrine or chloroquine, and even with a dosage of 1.0 g daily the blood concentration falls below assayable level 7 days after its administration ceases, while it cannot be detected in the urine after 9 days. It acts as a true causal prophylactic in infections with Pacific, Asian, American and also African strains of *P. falciparum*, exerting a highly selective action on the pre-erythrocytic forms and is an effective suppressant for B.T. malaria when given in appropriate dosage. For the treatment of overt attacks of M.T., B.T. or quartan malaria in semi-immune subjects in malarious areas such as labour forces and rural populations, a single dose of 300 mg of proguanil will usually suffice to produce clinical cure. Such treatment should cause a minimal degree of interference with premunity, is readily carried out and is satisfactory economically.

Overt attacks of B.T. malaria in non-immunes are clinically cured by a course of proguanil but relapses generally follow later. With the object of attaining radical cure in adults, 100 mg of proguanil, and 10 mg of pamaquin base or 20 mg of pentaquine base, is given thrice daily for 12 days. Bed rest is essential during this treatment. If this is not feasible and relapses are troublesome, an alternative course is 100 mg of proguanil thrice daily for 10 days, followed by a single dose of 300 mg of proguanil on the same day each week for 1 year.

Variable results have been obtained in the proguanil treatment of overt M.T. attacks in non-immunes in different countries, and the schizonticidal action of the drug appears to vary considerably with different strains of *P. falciparum* in regard to radical cure rate. For this reason, and because the clinical response is slower in M.T., B.T. and quartan malaria than with other schizonticides like quinine, mepacrine or chloroquine, it appears advisable to reinforce proguanil with mepacrine or chloroquine for the first day or two of treatment. A 10 day course of treatment with proguanil, 0.2 g thrice daily, reinforced with 0.3 g of mepacrine thrice daily on the first day of treatment only, has been advocated by Covell, Nichol and Shute on the grounds that there is a rapid clinical response, absence of relapses over a 3 monthly period and sterilisation of gametocytes. In strains, such as the Lagos strain which are less susceptible to the schizonticidal action of proguanil it is essential that radical cure of the overt attack should be attained, this is especially necessary in malarious areas where proguanil prophylaxis is in force for otherwise further overt attacks may be wrongly attributed to fresh infections when they are really recrudescences of the original infection in which parasitaemia had persisted to a submicroscopic density after the original clinical symptoms had temporarily disappeared.

Proguanil does not destroy M.T. or B.T. gametocytes in the human carrier, but it prevents the development of the sexual cycle in the stomach of the mosquito vector provided it is present in the imbibed blood—even in minute quantity. This effect is evident within 3 hours of administering 0.15 g to a human carrier, and may persist after the blood concentration is too low to be estimated. Toxic manifestations are very rare with the ordinary therapeutic dosage, with larger doses such as 0.5 g twice daily epigastric discomfort, vomiting and diarrhoea are occasionally noted and transient haematuria has been very rarely recorded. Large doses should be given with a copious draught of water after food.

General treatment—Rest in bed is essential during the febrile period, and is advisable for 3 days after the temperature reaches normal, or longer in cases with primary M T fever. A suitable aperient, such as magnesium or sodium sulphate, is administered at the onset of fever and should be repeated if necessary. During an attack of ague, hot drinks and plenty of blankets are necessary in the cold stage. Cold drinks, an ice cap and an aspirin-phenacetin mixture decrease discomfort in the hot stage. When the temperature exceeds 104° F tepid sponging is indicated. Drinks should be sweetened with sugar (4 oz daily). In the sweating stage, hot drinks are indicated, and bedclothes and pyjamas require changing. During convalescence, a well-balanced diet is essential. A tonic pill containing iron (Ferri sulph. gr. 3) is advisable thrice daily should there be anaemia, and, if it be severe, blood transfusion will accelerate convalescence. When malaria is the cause of anaemia, administration of antimalarial drugs is followed by a specific reticulocytosis reaching a maximum some 7 to 10 days later and, provided that the diet is well balanced and adequate in vitamins and blood-forming constituents, blood regeneration is generally rapid.

Treatment of ordinary overt attacks—As described above there is a choice of several different courses of treatment with quinine, mepacrine, chloroquine or proguanil, any one of these generally produces clinical cure of overt attacks of M T, B T or quartan malaria. Intensive quinine treatment (gr 30 daily) if continued for 3 weeks generally results in the radical cure of primary malignant tertian malaria. The use of quinine therapeutically in chronic recurrent or latent malignant tertian malaria is questionable owing to the possible precipitation of blackwater fever. The highest proportion of radical cures in M T malaria is probably obtained by intensive treatment with chloroquine or mepacrine, with mepacrine at least the duration as well as the intensity of drug administration is important. Though proguanil is effective in the radical cure of some strains of M T malaria (New Guinea strain) it fails with others (Lagos strain), for reasons already stated when treating overt M T malaria with proguanil it is better to combine it with mepacrine in the initial stages.

For the radical cure of B T malaria it is advisable to give one of the 8 amino quinoline compounds like pamaquin or primaquine with quinine or proguanil. The usual course advocated consists of quinine sulphate (gr 10) with 0.008 to 0.010 g pamaquin base thrice daily after food for 10 days (Sinton). Each standard tablet contains either 0.018 or 0.023 g pamaquin naphthoate (0.008 or 0.010 g base respectively), 3 are administered daily. Primaquine is said to be somewhat less toxic than pamaquin and a combination of quinine hydrochloride (gr 10), t.d.s., and primaquine base (total daily dose of 0.015 g) daily for 10 days gives excellent results. Patients should be kept in bed under strict medical supervision during such treatment. The dosage with children should be reduced in accordance with age and body-weight.

Treatment of acute pernicious malaria—In all cases of hyperinfection or with clinical manifestations suggesting acute pernicious malaria or where a patient is vomiting excessively or cannot swallow, intravenous injections of quinine bishydrochloride (0.3 g) should be given without delay. These injections can be repeated in 4 to 6 hours' time if necessary. As soon as possible the oral administration of quinine, mepacrine, chloroquine or proguanil in appropriate dosage should be commenced.

Intravenous quinine therapy is often a life saving procedure. The injection consists of gr 10 of quinine bishydrochloride in 10 ml or more of isotonic saline solution. Precautions to be observed are (1) sterility of the solution, (2) adequate dilution and (3) slow injection. At least 3 minutes should be taken, the reason being that too rapid injection may lead to lowering of blood pressure and occasionally to collapse. Adrenaline, however, should never be employed with the idea of preventing a fall in blood pressure.

Aseptic venous thromboses not infrequently follow such injections of quinine bishydrochloride but they are harmless and call for no treatment. No fatal results were recorded in many thousands of intravenous injections of quinine given to troops in New Guinea. Intramuscular injections of quinine should be reserved for those cases in which it is impossible to use the intravenous route. Though effective therapeutically, such injections are often painful, cause muscle necrosis and may result in a chemical or bacterial abscess. In young children or adults in whom intravenous injection is difficult, quinine can be given intramuscularly.

Mepacrine hydrochloride and Atebrin musonate can be used for intramuscular injection in a dosage of 0.3 g and 0.375 g respectively, and such injections may be repeated in 6 hours where necessary. Indications for their use are similar to those for intravenous quinine therapy, they should be replaced by oral medication with mepacrine or one of the other schizonticidal drugs as soon as possible. A total dosage of 1.0 g of mepacrine should not be exceeded in the first 24 hours of treatment. Chloroquine has been successfully used parenterally in solutions of the sulphate containing 40 mg of the base per 10 ml. The adult dose is 5 ml, i.e., 200 mg intravenously, repeated after 8 hours if necessary.

Apart from the immediate parenteral injection of quinine dihydrochloride or mepacrine hydrochloride it is most necessary in all hyperinfections including cerebral and algid malaria to combat dehydration and to maintain an adequate blood volume by the intravenous injection of large quantities of such fluids as isotonic saline (0.85 per cent) or glucose (5 per cent) given by continuous drip or intermittently. When there are algid manifestations or the blood pressure is unduly low, quinine bishydrochloride should be given intravenously in a pint of one of the above solutions in the first instance or mepacrine hydrochloride (0.3 g) intramuscularly be substituted. In cerebral malaria if the cerebrospinal fluid is under increased pressure, the withdrawal of 10 to 20 ml may prove useful. In malarial hyperpyrexia intravenous quinine should be combined with hydrotherapy as in the case of primary heat stroke. The naked patient is placed under a fan on a wire or rush mattress and covered with a sheet which is kept continually moist by spraying with ice-cold water. The rectal temperature is carefully noted and hydrotherapy stopped when it reaches 102° F.

The chief precipitating factor is the administration of quinine to a patient suffering from an ordinary attack of malaria fever. Mepacrine and proguanil appear to have less tendency to precipitate blackwater fever than quinine, possibly because they more frequently produce radical cure of M.T. infections. Where hæmoglobinuria follows pamaquin administration, there is generally an associated methæmoglobin-cythæmia; under such circumstances the condition is really one of pamaquin hæmoglobinuria due to idiosyncrasy or hypersensitivity to the drug.

At the onset of the attack blood examination may reveal parasites of *P. falciparum*, while in others *P. vivax*, *P. malariae* or *P. ovale* may be found; even so, the available evidence entirely supports the view that to develop true blackwater fever a patient must be suffering from a latent or an overt infection with *P. falciparum*.

Various theories, none of them very convincing, have been put forward to explain the hæmolysis. Some have ascribed it to a biological hæmolysin, and others think it may have an anaphylactic origin. Recently it has been suggested that red cells, modified by the malaria parasite and the administration of an antimalaria drug, form an autoantigen; this stimulates the formation of an autohæmolysin which causes intravascular hæmolysis (Gear). Prehæmolytic swelling of the corpuscle has been demonstrated in attacks of hæmoglobinuria induced experimentally by giving quinine to a patient of blackwater fever diathesis suffering from M.T. malaria; after cure by mepacrine quinine administration no longer produced hæmoglobinuria.

Pathology.—Morbid anatomy.—The skin is jaundiced, the blood watery and the serum sometimes tinged with hæmoglobin. The liver is enlarged and soft, the bile thick and tarry, the spleen big and its pulp almost diffuent, and the kidneys are dark, swollen and congested. Microscopically, hæmosiderin is found in the liver and spleen, in which malarial pigment (hæmatin) may also be evident. Eosinophilic granular debris blocks a variable proportion of the renal tubules, and there is toxic degeneration and desquamation of the cells of the convoluted tubules. There is cloudy swelling and necrosis of liver cells, especially in the centre of the lobule, while malarial pigment may be found in Kupffer's cells.

Clinical pathology.—Malarial parasites, which are present in blood smears at the beginning of the attack, generally disappear after 24 hours, and are not demonstrable at necropsy. The urine shows albumin, oxyhæmoglobin and urobilin in excess; methæmoglobin is generally also demonstrable, especially in acid urine. Bile is present only in the more severe cases, and ketones may also appear. The characteristic sediment consists of brown granular debris and granular casts. Red blood corpuscles are scanty or absent.

The plasma contains hæmoglobin and later methæmalbumin. Hyperbilirubinaemia is characteristic. The blood urea is markedly raised.

Renal failure depends on several factors, chief of which is decreased glomerular filtration. According to Macgrath and others, tissue anoxia suffices to explain the tubular lesions, while reduction or absence of glomerular filtration leads to decreased urinary flow and anuria. Severe intravascular hæmolysis results in shock and reflex spasm of the intrarenal vessels; cortical ischæmia follows, the glomeruli which are normally responsible for water secretion are by-passed and oliguria and anuria result. In other cases polyuria is marked; here interference with glomeruli responsible for water secretion must be slight and the high blood urea which is present results in increased diuresis if the fluid intake be adequate. Where anuria results, renal acidosis develops; this is associated with lowering of the CO₂ combining power of the plasma, a decrease in serum calcium and an increase in the blood phosphorus. Anæmia is frequently profound, and in severe cases 50 per cent. of the corpuscles may be destroyed overnight. A study of the excretion curves of urinary hæmoglobin shows that several distinct intravascular hæmolyses may occur.

Results of hæmoglobin disintegration.—Hæmoglobinuria ensues whenever the concentration of the extra-corpuscular hæmoglobin exceeds the renal threshold. It

is unknown whether actual blockage of the tubules with pigmented debris follows or precedes the failure of renal secretion, but when many nephrons are blocked restoration of renal function will be correspondingly more difficult. Provided urinary secretion continues, red urine containing unchanged oxyhæmoglobin is generally found when the reaction is alkaline, whereas porter-coloured or black urine is generally passed if the reaction be acid due to the conversion of much of the oxyhæmoglobin into methæmoglobin. Part of the circulating hæmoglobin is absorbed directly by the reticulo-endothelial cells, with the production of hæmosiderin and bilirubin. The resulting hyperbilirubinæmia accounts for the hæmolytic jaundice and also for the pleocholia which is responsible for the bilious vomiting and dark-brown stools, while the absorption of surplus stercobilinogen causes urobilinuria, especially in the presence of liver damage. Finally, any residual circulating hæmoglobin is split into globin and hæm or reduced hæmatin, which is oxidised to hæmatin and unites with serum albumin to form methæmalbumin (Fairley).

Symptoms.—No recognisable pre-blackwater fever stage exists. The patient rightly thinks an attack of malaria is impending, for which quinine, as a rule, is taken. The onset, which generally occurs within 24 hours, but may be delayed for 1 to 2 weeks, is usually sudden, with chill and loin pain, but in mild cases red or black urine may be the first indication. A rise of temperature is almost invariable, rigor is common, and nausea, bilious vomiting and epigastric discomfort are characteristic. The urine, which may be reddish at first, generally becomes port-wine or porter coloured, presenting the characteristics described. As the condition progresses, polyuria, oliguria or anuria may develop. Within a few hours yellowish discoloration of the skin and conjunctivæ is apparent. This increases in intensity if hæmoglobinuria continues, but only in the severest cases is bile found in the urine. The pulse is rapid and of low tension at first, and the blood pressure in severe cases is markedly depressed (S/D equals 80/50) at onset, though later it rises. There may be severe headache, photophobia, great restlessness, anxiety, pallor, cold extremities and thread-pulse occasioned by the rapidly developing anæmia. Hiccough and Cheyne-Stokes breathing may also develop in severe cases. As many as 2,000,000 red cells per c.mm. may be destroyed in 24 hours. The spleen and liver are generally demonstrably enlarged and tender, and may cause discomfort; the former decreases in size during the attack. Localised tenderness over the distended gall-bladder may also occur and loin pain, due to renal involvement, is common. The fever at onset resembles a malarial paroxysm, is highest at first, becomes intermittent or remittent later, and generally declines in 3 to 4 days, as the vomiting subsides and the urine clears. Post-hæmoglobinuric fever may appear after hæmoglobinuria has ceased and persist well into convalescence. Hyperpyrexia may develop, especially in the late phases of the disease, while some cases show a marked tendency to hæmorrhages in the skin and the gastro-intestinal tract.

Several different clinical types are encountered: (1) Mild hæmoglobinuria, especially common in children, in which blood pigment in the urine may only be found for a few hours and perhaps only in one or two specimens. The hæmoglobinuria associated with hyperinfection in M.T. malaria may fall into this category. (2) Severe hæmoglobinuria, associated with the clinical features already described. These are separated into two groups: (a) the polyuric type in which renal excretion is well maintained despite evidences of nitrogenous retention; and (b) the oliguric and anuric types. Catheterisation at first shows small quantities of highly albuminous, perhaps bile-stained urine, followed later by complete suppression. Anuria may occur early, and is associated with a normal or subnormal temperature. Hepatogenous jaundice may also develop. Life may be prolonged for many days, and death may occur with renal acidosis and uræmia. Toxic features are common in both these types. (3) Intermittent hæmoglobinuria, in which blood pigment is present in the urine from time to time, while in the intervals it disappears entirely. In these cases

the temperature may continue for some time, post-haemoglobinuric fever is common, and icterus and anaemia are well marked

Complications—Complications include anuria, post-haemoglobinuric fever, anaemia, retinal haemorrhages, biliary colic, pigment calculi and cholecystitis

Course and Prognosis.—About 10 per cent of cases relapse during the course of an attack (Ross). Convalescence may be prolonged, owing to anaemia and transient renal dysfunction, but there is no evidence that chronic nephritis results. The outlook depends to a considerable extent on the rapidity of the haemolysis and the quantity of corpuscles destroyed. The mortality rate varies from 15 to 40 per cent, and though some cases are probably doomed from the onset, in others modern therapy and good nursing favourably influence the course of the illness. Thus, in a recent series receiving large blood transfusions and alkali medication the mortality was only 15.0 per cent. Unfavourable features include rapidly increasing jaundice, grave anaemia, severe hiccough, anuria and hyperpyrexia.

Treatment—PROPHYLACTIC—The prophylaxis of blackwater fever is the cure of M.T. malaria. As a result of measures designed to cure M.T. infections in troops in New Guinea, the incidence of blackwater was reduced to less than 1 per 3,000 cases of malaria. In malaria patients in whom there is a previous history of blackwater fever, abundant fluid with citrates should be given and quinine avoided, proguanil, chloroquine or mepacrine should be substituted in treating overt attacks.

CURATIVE—In most cases of blackwater fever parasites are not plentiful and rapidly disappear from the blood, and therefore specific drug treatment can generally be postponed until convalescence. If, however, haemoglobinuria follows intravenous quinine injections for hyperinfection, antimalarial drug therapy must be continued, and abundant fluid and alkalis administered. In the absence of knowledge concerning the rational control of haemolysis in blackwater fever, the therapeutic indications are to combat anaemia and heart failure on the one hand, and renal acidosis and uraemia on the other, for these are the chief causes of death. Measures directed to these ends include absolute rest in bed, fluids by different routes, administration of alkalis and blood transfusion.

Blackwater fever patients should not be moved unless it is impossible for them to be treated where they are. Careful nursing is most important, and the patient should be kept recumbent throughout the illness. In collapsed cases with low blood pressure, early blood transfusion, warmth and elevation of the foot of the bed are advisable. The diet should consist of bland fluids, fruit juices and sweetened drinks, later, milk, fruit jellies, junket and Benger's are allowed. Copious fluids are given by mouth, they should contain sufficient sodium bicarbonate or potassium citrate to combat acidosis and alkalinise the urine. Once established, the alkaline reaction should be maintained until haemoglobinuria has ceased, provided symptoms indicative of alkalosis, such as muscular cramps, tetany and Trousseau's sign do not supervene. Rarely alkalosis may develop while the urine is still acid in reaction, estimations of the plasma bicarbonate afford valuable data in this regard and should be carried out when practicable. Macgrath and Havard consider that if an acid urine persists after 20 g of alkali have been given in the 24 hours no further alkali should be administered.

If vomiting proves troublesome, gastric lavage may be practised and fluids containing alkalis and glucose are given intravenously. In cases in which the urine is acid in reaction, 1 pint of bicarbonate of soda (150 grains to 1 pint) may be immediately injected intravenously. This solution should be sterilised by filtration or by adding the weighed bicarbonate to cooling boiled water, since boiling is liable partially to convert it into the toxic carbonate. Alternatively 10 ml of a saturated solution of sodium bicarbonate and 10 ml of sodium lactate (four molar) may be injected, the latter exerts a more delayed and sustained effect than does the more rapidly acting bicarbonate. Such injections may be repeated as required.

It is always important to prevent dehydration, assist the heart and maintain a good urinary output. For this purpose a sterile solution of 5 per cent. glucose should be given intravenously when required, either intermittently or by continuous drip; as much as 2000 ml. may be administered in 24 hours when fluid is not being taken satisfactorily per os.

Blood transfusion is the best means of combating anæmia, anoxæmia and circulatory failure, and it also probably assists in combating renal failure by increasing glomerular filtration pressure. Up to 2 pints may be given intermittently as required, or better still, a reasonable blood count can be maintained by continuous intravenous drip administration. When the hæmolytic is severe and prolonged, or when the hæmoglobinuria is of intermittent type, many pints of blood may be necessary. In the polyuric type, blood transfusion is a life-saving procedure but its effect in the anuric type is more uncertain, the renal damage often proving irreversible despite all treatment. One reason for this is that blood transfusion is not undertaken early enough, i.e. at the onset of the shock and circulatory failure which accompanies any severe intravascular hæmolytic.

Treatment of anuria is largely conservative. Diuretics are ineffective. A fluid intake-output record must be kept, included in which should be all fluids administered parenterally. The latter should be limited to produce a slightly positive fluid balance, otherwise the patient may become waterlogged and develop pulmonary œdema.

Institution of the Borst and Bull¹ régime consisting of the intra-gastric administration of a litre of 40 per cent. glucose in arachis oil and gum acacia given daily, plus a volume of water equivalent to fluid lost may be worth a trial. The prognosis in the anuric patient is bad, but most unexpected recovery may occur, followed by a short period of polyuria, and the passage of unconcentrated urine.

Convalescence.—Once hæmolytic has ceased, marked reticulocytosis, followed by rapid blood restoration, proceeds automatically in the well-fed European; iron in adequate dosage is indicated in convalescence, and liver extract or Marmite may prove necessary in peasant populations living on diets deficient in good animal protein. In all cases blood transfusions are advisable if the rate of blood regeneration is unsatisfactory.

As mepacrine, chloroquine and proguanil appear to have less tendency to induce blackwater attacks than quinine or pamaquin, a full course should be given with one or other of these drugs during convalescence with the object of attaining radical cure.

LEISHMANIASIS

Leishmaniasis is the term applied to a group of diseases caused by parasites of the genus *Leishmania*. Some of these are general infections, others are local. Of the first, there is kala-azar due to *Leishmania donovani* (Laveran and Mesnil, 1903), and infantile or Mediterranean kala-azar, caused by *L. infantum* (Nicolle, 1908). Both morphologically and serologically they appear to be the same parasite, and there seems to be little reason for separating them. Both Mediterranean and Sudanese kala-azar, however, are much more difficult to cure than the Indian type. Oriental sore, due to *L. tropica* (Wright, 1903), and American dermal leishmaniasis, due to *L. braziliensis* (Vianna, 1911), are generally regarded as distinct species, belonging to the second group.

KALA-AZAR

Definition.—Kala-azar, or black fever, is a specific disease associated with enlargement of the spleen and liver, anæmia, great emaciation and irregular fever of long

¹ *Lancet*, 1953, ii, 791

duration, caused by the protozoon *L. donovani*, present in the blood and reticulo-endothelial cell system.

Ætiology.—The disease has definite geographical limitations, being commonest in India, Assam and the Mediterranean littoral, 90 per cent. of these cases occurring in children; it is also found in China, Indo-China, the Sudan, Abyssinia, Russian Turkestan and Mesopotamia. Natives appear more susceptible than Europeans, probably owing to different habits of life. In Assam villages the introduction of an infected case generally precedes other cases, and often it appears to be a house infection (Rogers). Children and young adults are specially liable, and males appear more susceptible than females. In the Mediterranean area very young children and dogs suffer from kala-azar, whereas in India and North China the disease occurs in older people and rarely in dogs.

The non-flagellate stage of the parasite is a small oval body, 2 to 5 μ long by 1 to 2 μ broad, containing (1) a large round laterally placed nucleus (macronucleus or trophonucleus), staining bright red with Romanowsky's stain; and (2) a kinetoplast (micronucleus, centrosome) which is usually rod-shaped, stains a deep reddish-purple and has one end pointing toward the nucleus. It can be cultivated on rabbit-blood agar (N.N.N. medium) if grown for 2 to 3 weeks at room temperature (72° to 77° F.), provided the culture material has not been contaminated. During growth, *Leishmania* bodies develop into leptomonads measuring up to 24 μ in length, with a flagellum and centrosome at one end and a central macronucleus.

This flagellate represents the stage attained in the insect vector—i.e. some sand-fly of the genus *Phlebotomus*. If after an infective feed on blood containing *L. donovani*, the sand-flies (*Phlebotomus argentipes*) are nourished on raisins and not on blood, the flagellates rapidly multiply and fill the anterior portion of the stomach, block the pharynx and extend forward to the buccal cavity and mouth parts. Blocked sand-flies cannot ingest blood, and in an effort to do so discharge flagellates into the skin. Highly successful experimental transmission to mice, hamsters and man has recently been reported by Swaminath, Shortt and Anderson using blocked sand-flies, and the problem of kala-azar transmission has at last been finally solved. The chief vectors are *P. argentipes* in India, *P. perniciosus* in the Mediterranean area, and *P. chinensis* in North China. Though viable *L. donovani* may be discharged from ulcers in the intestine, naso-pharynx or bladder of a kala-azar patient, it is most unlikely that man ever becomes infected except by sand-flies.

Pathology.—Leishman-Donovan bodies multiply by fission, and are found crowded together in endothelial cells of the blood vessels and lymphatics, especially those of the spleen, liver, bone marrow and skin. They are also found in the mononuclear and polymorphonuclear leucocytes in the blood. At necropsy emaciation is marked, the spleen and liver are generally enlarged, while dropsical effusions and intestinal ulceration may occur. The spleen is at first soft, pulpy and friable, and later it becomes hard and fibrous; the capsule is thickened, and perisplenitis and infarcts may also be found. The liver is firm and friable, the capsule is thickened, and fatty degeneration and a nutmeg appearance are common; cirrhosis may eventually result. The bone-marrow is generally red and soft, showing a decrease of fat. The mesenteric glands are often enlarged, presenting a central necrosis. The heart is dilated and flabby, while the entero-colon may show superficial or deep ulcerations; the latter at least are of dysenteric origin.

Symptoms.—The incubation period is probably from 1 to 4 months, but cases may occur 1½ years after exposure. The onset may be sudden, with fever simulating malaria or typhoid, or insidious. Often in febrile cases the diagnosis is not made until relapses occur and the more classical features of the disease develop. These may be classified as follows: (1) Irregular, remittent or intermittent pyrexia, which, though not necessarily high, is characteristic. Periods of apyrexia spontaneously develop, and may lead to confusion with Malta fever. A double daily rise may occur

in the afternoons and evenings, but this may also be noted in other diseases and is not pathognomonic. (2) Loss of hair and deepening colour or pigmentation of the skin—hence the name black fever. (3) Anæmia, with the characteristic blood changes. (4) Rapid loss of weight and cachexia. (5) Splenomegaly, which may be the first sign or only be noted after 1 to 2 months of fever. In the early stages the spleen feels soft and doughy, but not tender; later, it hardens and may reach very large dimensions. (6) The liver is generally palpable (88 per cent.), presenting a sharp lower edge. (7) Diarrhœa. There is a good appetite associated with poor digestion, which itself may lead to intermittent diarrhœa (Napier). If blood and mucus be present, intercurrent dysentery should be suspected. (8) Other features include night sweats, persistent irritating cough, palpitation, dyspnoea, low blood pressure, *i.e.* below 100 mm. of mercury, œdema of the extremities and occasionally puffiness of the face. Amenorrhœa often develops, but conception may occur with congenital transmission from the mother (Low and Cooke). The blood changes, which include anæmia, leucopenia and reduction in platelet count, are due to replacement of both the leucoblastic and erythroblastic marrow by clasmatoctytic tissue. The hæmoglobin is often proportionally reduced, so that the colour index may equal 1.0; in other cases it is 0.7 or 0.8. The blood picture may show anisocytosis, poikilocytosis, polychromasia and normoblasts. The leucopenia is extreme, often sinking to 2000 per c.mm.; in 80 per cent. of cases it is less than 4000 per c.mm. The differential count reveals a relative increase in lymphocytes and monocytes, with a decrease in neutrophils and eosinophiles. In some instances true agranulocytosis may develop. The coagulability of the blood may be prolonged, the calcium, blood sugar and serum albumin are reduced, and the total globulin content of the blood is raised, euglobulin increasing at the expense of the pseudo-globulin fraction.

Complications and Sequelæ.—Owing to debility and bone-marrow involvement with leucopenia, the resistance to bacterial infections is markedly decreased, and broncho-pneumonia, lobar pneumonia and tuberculosis are common causes of death; otitis media and cancrum oris may occur, especially in children. Watery diarrhœa and intercurrent dysentery are frequent. Purpura, epistaxis, bleeding from the gums and melæna may be encountered. The sequelæ include chronic splenomegaly plus severe anæmia and cirrhosis of the liver, sometimes associated with ascites. Jaundice frequently appears within 3 months of treatment and may persist for several months.

Post-kala-azar dermal leishmaniasis is being increasingly recognised. Areas of depigmentation appear about a year after antimony injections and papillomatous nodules, in which leishmania can be found, occur the following year. A xanthoma-like condition is also described, but ulceration never occurs. Parasites are demonstrable in smears and culture and apparently they are mainly confined to the skin, as splenic puncture generally yields negative results. The condition may also appear in persons who give no history of previous kala-azar or of treatment. When the face is affected the condition has to be differentiated from leprosy. In the Sudan, non-ulcerative papillomatosis and nodules of the skin are common in kala-azar patients, and muco-cutaneous lesions similar to espundia have been reported (Kirk).

Diagnosis is generally dependent on the demonstration of *L. donovani* in smears from lymphatic glands, sternal marrow, the liver or spleen or cultures on N.N.N. medium obtained from the peripheral blood. Parasites are less common in the peripheral blood in Mediterranean than in Indian kala-azar. Aspirated material for microscopical examination must be collected in an absolutely dry syringe. Sternal marrow is satisfactory for microscopical examination or culture; sternal puncture is free from the danger of hæmorrhage and causes little pain. Enlarged lymphatic glands along the saphenous vein or elsewhere may be punctured with a dry hypodermic needle without a syringe, and the juice which enters the needle blown on to a slide and stained.

The formol-gel or aldehyde test of Napier is of considerable value in the diagnosis of kala-azar, especially when the result is positive and associated with a leucopenia. The test is performed by adding 1 drop of commercial formalin (30 per cent formaldehyde) to 1 ml of clear serum, which is immediately shaken and left at room temperature. When the reaction is positive the serum immediately becomes viscous, and within 1 or 2 minutes assumes a whitish opalescent appearance and sets so that the tube can be inverted without spilling. In from 3 to 20 minutes it forms a solid opaque coagulum like the white of a hard-boiled egg. For the first 3 months the reaction is of doubtful value, but after this it is generally positive.

Kala-azar has to be differentiated from the febrile splenomegalies of the tropics, especially chronic malaria, undulant fever and enteric fever, schistosomiasis, Banti's disease and leukaemia must also be considered, and owing to the danger of hæmorrhage in the latter disease splenic puncture should never be undertaken until blood examination has excluded it. In childhood Mediterranean kala-azar has to be differentiated from Cooley's anaemia, commonly found in Greece, von Jaksch's anaemia and acholuric jaundice.

Course and Prognosis—Bentley showed in the Assam epidemics, prior to the introduction of antimony, that the disease lasted 1 to 2 years in chronic cases. The mortality rate, if untreated, is about 90 per cent. Intercurrent disease, severe intestinal symptoms and cirrhosis with ascites are of grave significance. Modern therapy generally results in recovery, provided the condition is not too advanced and intercurrent disease absent.

Treatment—**PROPHYLACTIC**—Segregation and treatment of the sick, and abandonment of infected houses and rebuilding at distances not less than 300 yards have been effective in India. Destruction of the sand fly vector by spraying its breeding-places with D D T is indicated. For other measures, see phlebotomus fever (p. 189).

CURATIVE—The patient is put to bed on a milk or light diet adequate in vitamins. Intercurrent disease and complications should receive appropriate treatment. Three groups of specific drugs are known, namely, the trivalent antimony compounds, the pentavalent antimony compounds and certain aromatic diamidines introduced by Yorke and Evans. The effects of specific drug treatment are to reduce the temperature to normal, decrease the splenomegaly and hepatomegaly, increase body weight and restore the leucocytes to normal numbers. Cure is indicated by an absence of clinical symptoms for 6 months, a negative aldehyde test, an increase in serum albumin associated with a decrease in total globulin involving the cuglobulin fraction and a permanent disappearance of parasites.

(1) *Trivalent antimony compounds*—Antimony potassium tartrate or antimony sodium tartrate are administered intravenously, as described in the section on schistosomiasis (p. 321), the only difference being that a longer course totalling some gr. 40 to 60 is required.

(2) *Pentavalent antimony compounds*—These have replaced the trivalent antimony derivatives owing to their more rapid action, reduced toxicity and superior parasitocidal action. They include Neostam, Ureastibamine, Neostibosan and Pentostam. The adult dosage of the first two is 0.1 g. initially, 0.2 g. as a second dose and 0.25 g. for each subsequent injection. In the case of Neostibosan an initial dose of 0.2 g., with subsequent doses of 0.3 g. is advised. Debilitated patients require small doses, while children, although tolerating proportionally larger doses than adults should receive smaller initial doses. The length of the course varies from 10 to 15 daily injections. Toxic features include nausea, vomiting, giddiness and more rarely diarrhoea, hepatitis and jaundice, and an anaphylaxis-like syndrome characterised by urticaria, puffiness of the face and cardio-vascular collapse. The response of Indian and Chinese kala-azar to Neostibosan is in most instances highly satisfactory, but Mediterranean kala-azar requires at least three times as much of the drug to effect

a cure. Sudanese kala-azar is even more refractory, and complications, such as intractable diarrhoea, hæmorrhages, cancrum oris and lobar pneumonia, are particularly prone to develop.

Pentostam (sodium stibogluconate) contains 100 mg. of pentavalent antimony per ml., and the normal adult course of treatment consists of 6 to 10 injections of 6 ml. each. It can be given either intramuscularly or intravenously without undesirable local or systemic effects. The response to the drug is generally rapid, the temperature falling within 4 days. In India and China the recovery rate has been high, and in Mediterranean infantile kala-azar and Sudanese kala-azar it is reported to be effective.

(3) *Aromatic diamidines*.—Stilbamidine has been used effectively in different types of kala-azar but its use has now been abandoned owing to the incidence of severe toxic complications, such as delayed acute yellow atrophy of the liver and central nuclear degeneration, especially involving the 5th cranial nerve. It has been replaced by pentamidine isethionate (given in doses of 2 to 4 mg. per kg. body weight), which appears to be effective therapeutically in kala-azar without producing undesirable toxic features; it should be specially useful for cases which are antimony resistant. The course of treatment is similar to that advised for trypanosomiasis (see p. 273).

AMERICAN DERMAL LEISHMANIASIS

Synonyms.—Espundia; Uta; Pian Bois; Pian Cayenne; Forest Yaws; Bosch Yaws; Bubas Braziliana.

Definition.—An infective granuloma due to *Leishmania braziliensis*, producing cutaneous nodules and ulcers on exposed surfaces; the buccal and nasal mucous membranes may be extensively involved, and also the lymph glands and lymphatics.

Ætiology.—The disease is found in South and Central America with the exception of Chile. It is specially frequent amongst wood-cutters and people living in forests. Sand-flies are almost certainly the transmitting agent. Morphologically, *L. braziliensis* is similar to *L. tropica*, but differs in the fact that it involves mucous membranes in 10 to 20 per cent. of cases in addition to the skin.

Symptoms.—The incubation period is about 2 months. The lesion originates as an itching papule, which may develop into a blind nodule or may ulcerate, producing fungoid granulations. In 10 to 20 per cent. of cases, ulcers appear at the margins of the mouth and nose, often subsequently involving their mucous surfaces, the larynx and nasal septum. Fever, joint pains and bronchitic symptoms now appear, but many years may elapse before the patient succumbs to intercurrent disease or cachexia.

Diagnosis.—Demonstration of the parasites, either in scrapings from the spreading margin of the ulcer or by culture, completes the diagnosis. Syphilis, rodent ulcer, leprosy and tuberculosis closely resemble the destructive form of *L. braziliensis*, which, however, never involves bone.

Prognosis.—This is only dangerous to life if the mucous membranes be involved (10 to 20 per cent.). If untreated, such patients die of intercurrent disease like pneumonia.

Treatment.—In South America the trivalent antimony compounds, such as tartar-emetic and subophen (Neo-antimonan; Guadin), appear to be preferred to the pentavalent antimony compounds. Otherwise the treatment is similar to that outlined for kala-azar and oriental sore.

ORIENTAL SORE

Synonyms.—Aleppo Sore; Baghdad Button; Delhi Boil; Biskra Button; Ashkabad Sore; Pendeh Sore; Bouton d'Orient.

Definition.—An infective granuloma of the skin and subcutaneous tissues caused

by *L. tropica* producing either a "dry" type of chronic papular lesion with late ulceration, or a "moist" type of papular lesion with early ulceration

Ætiology—Cutaneous leishmaniasis is common in Mesopotamia, Arabia, Persia, Central Asia (Russian Turkestan), North-West Frontier of India, Asia Minor, Northern Africa, Egypt, the Sudan, Nigeria, Spain, Italy and Greece

The "dry" type is urban in distribution occurring in cities like Baghdad, Delhi and Lahore. Practically nothing is known regarding its reservoir hosts, though, wherever it occurs, sand flies (*P. papatasi* and *P. sargenti*) are common. The remarkable development into virulent flagellates occurring in the mid gut and extending forward into the proboscis after feeding them on oriental sores indicates that these insects are transmitters. The disease has also been transmitted by rubbing into the excoriated skin a saline extract of crushed *P. papatasi* sent from an endemic area. The disease is auto inoculable, but not through the unbroken skin. It is possible that occasionally it may be transmitted by personal contact with an infected case. Dogs, cats, guinea pigs and mice are susceptible.

The "moist" type is rural, occurring in open or desert country. In Middle Asia the endemic foci are rural settlements adjoining the desert, here desert sand-flies (*P. caucasicus* and *P. papatasi*) breed exclusively in the burrows of wild rodents (gerbils), which often have sores on their ears due to *L. tropica*. It has been conclusively proved that these infected gerbils serve as reservoir hosts for cutaneous leishmaniasis of "moist" type which is transmitted to man by sand flies breeding in the burrows of these rodents.

Pathology—Infective granulomata are produced, sections showing atrophy of the epidermis infiltration of the corium and its papillæ with lymphocytes, plasma cells and macrophage endothelial cells containing *L. tropica*. If the nodule ulcerates secondary bacterial infection ensues destructive and degenerative changes predominate, and leishmania become scanty. From the histopathological viewpoint acute and chronic oriental sores differ in the intensity and degree of the inflammatory process. In secondary lesions appearing later, the infiltration has a tuberculoid structure with few or no parasites, while the keloid type may show epithelial cell nests. Unlike the American form the mucous membranes are rarely involved.

Symptoms—The incubation period for the "dry" type with late ulceration is 2 to 6 months. The lesion commences as a small red papule which gradually enlarges softens and becomes purplish, glazed and scaly, being surrounded by a narrow dull red zone of inflammation. This may remain as a sort of blind boil for a year or more before disappearing, or, especially if injured, it may become covered with a yellow crust and ulcerate in 3 or 4 months the ulcer having well defined rounded edges and a granulation tissue base exuding thin pus. Under these circumstances there may be some enlargement of the neighbouring lymph glands (10 per cent). The sores may be single or multiple, as many as 35 having been recorded and are common over exposed parts, especially the hands, wrist, forearms, ears, nose, face, feet and legs. Parasites are numerous in these lesions, and the virulence to mice is low.

The "moist" form has a short incubation period of 1 to 6 weeks, and rapidly ulcerates in 1 to 2 weeks. Lymphangitis is common (70 per cent) secondary bacterial infection frequently occurring. Parasites are scanty and the virulence for mice is high. The duration of the lesions is less than 6 months.

Since infection or recovery from one form does not confer immunity to the other, it is probable that the two types of lesions are dependent on infection with different strains of *L. tropica*.

Various other forms of dermal leishmaniasis due to *L. tropica* have been described. They include (1) small firm discrete nodules occurring in the course of the lymphatics, (2) warty or papillomatous outgrowths which may resolve or ulcerate, (3) lupus like nodules which may implicate the cheek and (4) a keloid form characterised

by raised, shiny soft masses of infiltrated tissue covered by pinkish skin which gradually resolve without ulceration

Diagnosis—This is dependent on demonstrating the parasite. If ulceration has occurred, the skin at the edge of the ulcer should be sterilised with iodine, allowed to dry, punctured with a glass pipette, and the material so obtained inoculated on to N N N medium. Bacterial contamination prevents growth. Direct microscopical examination of this material often shows *L. tropica* in the endothelial cells.

Prognosis—The condition is practically never fatal even when untreated, but under these circumstances it may last 18 months, after which the patient generally possesses an immunity.

Treatment—**PROPHYLACTIC**—Sand flies and their breeding grounds should be eradicated. (See phlebotomus fever, p. 189)

CURATIVE—In cases which have been secondarily infected, hot boracic fomentations or antiseptic dressings should be applied until sepsis is controlled and the crusts separate. Sulphonamides or penicillin may be helpful in cases in which the secondary infection is difficult to clear up. Such forms of treatment as carbon dioxide snow, radiotherapy, radium, zinc ionisation and diathermy are useful as well as local applications of ointments containing methylene blue, iodoform, salicylic acid, protargol or Rivanol. Good results have been claimed for Orisol ointment containing berberine sulphate, and dithranol (Derobin, Cignolin) paint, applied with a camel hair brush and strictly confined to the ulcer surface. Russian investigators advise infiltration with 5 per cent mepacrine injected at several points, later a 10 per cent mepacrine ointment may be used.

Vaccines have their advocates. Neostibosan or Pentostam is also worthy of trial when multiple lesions are present.

TRYPANOSOMIASIS

A group of diseases caused by flagellate parasites of the genus *Trypanosoma*. In Africa man may be infected with *T. gambiense* or *T. rhodesiense*, and in South America with *T. cruzi*. Trypanosomes also produce disease in animals, the most important being nagana affecting horses, dogs, cattle and wild game in Africa caused by *T. brucei*, which is probably identical with *T. rhodesiense*. *T. evansi* produces surra and *T. equiperdum* dourine, the latter disease being transmitted during coitus.

AFRICAN TRYPANOSOMIASIS

Synonym—Sleeping sickness

Definition—This disease, transmitted by the bite of tsetse flies, is caused by *T. gambiense* (Dutton, 1902) or *T. rhodesiense* (Stephens and Fantham, 1910). After initial invasion by trypanosomes, blood infection ensues with adenitis, irregular remittent fever, rapid pulse, œdema and circinate erythematous rashes, later a meningo-encephalitis results with lethargy, mental and physical degeneration, tremors, shuffling gait, convulsions, coma and death. Mild cases, with headache and slight fever, are common.

Ætiology—The disease is limited geographically to areas where the tsetse fly abounds and occurs in Western and Central Equatorial Africa, including the Congo, Uganda, East Africa, Rhodesia, Nyasaland, etc. Natives and whites are both affected and children and adults of both sexes prove equally susceptible. The two species of trypanosome are indistinguishable in human blood, they possess a nucleus, a posteriorly situated blepharoplast and a flagellum. *T. rhodesiense* is identified by inoculating blood into white rats, when posterior nuclear forms develop, this so rarely occurs with *T. gambiense* that the test is one of real value in distinguishing these two trypano-

somes Furthermore, *T gambiense* manifests an uncertain pathogenicity to laboratory animals, and is relatively insusceptible to the action of normal human serum Glossinæ take up trypanosomes from the blood during biting, these multiply in the gut and pass forward via the proventriculus and salivary ducts to the salivary glands, where further development ensues Glossinæ become infective in 3 to 7 weeks and remain so for life, they bite mainly in the daytime *T gambiense*, the central African type, is transmitted by *G palpalis* and *G tachinoides*, possibly the natural reservoir of infection is game, such as the reed and bush buck, etc., encountered near lakes and rivers by which these flies live, depositing their larvæ in shady, sandy soil Man contacts these two riverine species repeatedly at fords, washing places, water points and in shaded villages, and as he seeks water and shade at the time of the day when these tsetse flies are most active, repeated and close proximity with the fly is assured *T rhodesiense*, on the other hand, is spread by *G morsitans* and *G swynnertoni* which are widely distributed independently of water The reservoir of infection is the infected game of the area Bruce identifies this disease with nagana and regards *T rhodesiense* as identical with *T brucei* As the pathology and symptomatology produced by the two African trypanosomes are similar they may be considered together

Pathology—The lymph glands, which are at first swollen, congested and hæmorrhagic, later undergo degenerative changes and extensive fibrosis Enlargement of the spleen due to lymphoid hyperplasia and proliferation of endothelial cells also occurs, while thickening of the capsule is common In the late stages trypanosomes are demonstrable in the intercellular spaces of the brain and cord, the microscopical appearances of which resemble those of meningo encephalitis and meningo myelitis Mott has stressed the resemblance to general paralysis, perivascular lymphocytic infiltrations being invariable Neuroglial cell overgrowth is also characteristic, and diffuse glial proliferation affects both the white and grey matter in the cord the ganglion cells show chromatolysis of their nuclei, most marked in the cerebral cortex and endothelial proliferation in the arteries may occur

Symptoms—Two phases are recognised (I) a stage of trypanosome fever when the trypanosomes are demonstrable in the blood and gland juice, (II) the sleeping sickness stage when the cerebrospinal fluid contains lymphocytes, globulin and perhaps trypanosomes The incubation period probably varies from 1 to 3 weeks, and occasionally an intense local reaction follows at the original inoculation site In many respects trypanosomiasis resembles syphilis (I) *Trypanosome fever*—This is invariably seen in Europeans, but not always in natives Its main features are (1) an irregular remittent or intermittent temperature low in the mornings, higher at night, apyrexial periods may occur, lasting for weeks (2) A low tension, rapid pulse of 100 to 120 per minute, which tends to persist despite a fall in the temperature (3) An increase in the respiratory rate to 20 or 30 per minute (4) Patches of circinate erythema, involving mainly the trunk (5) Localised puffiness and œdema involving the feet, legs and face the skin may be dry and irritable (6) Polyadenitis enlargement of the posterior cervical glands (Winterbottom's sign) is very characteristic, the epitrochlear, axillary, supraclavicular and axillary glands may also be involved, they are soft, elastic, not tender and do not coalesce or suppurate (7) An enlarged spleen which is generally palpable (8) Deep hyperæsthesia, especially over bones like the tibia and manifesting a definite latent period (Kerandel's sign) Long latent periods of several months (rarely several years) may elapse before the central nervous system becomes involved and probably some cases undergo spontaneous cure where the virulence of the trypanosome is low Once the stage of sleeping sickness has become definitely established, the untreated patient rarely survives for longer than a year (II) *Sleeping sickness*—In the earliest phase the patient may complain of headache, lack of concentration disinclination for work and insomnia, associated with loss of weight, enlargement of lymphatic glands and slight

tremor of the tongue. In the *intermediate phase* the countenance becomes sad, apathetic and morose, laziness and emotional instability increase, and the patient is always dropping off to sleep, even in tropical sunlight or when eating. The speech becomes mumbled and slow, the gait shuffling and fibrillary tremors of the tongue, lips and hands develop. The reflexes are exaggerated and Romberg's sign is present. In the *final phase* all these symptoms become more pronounced; muscular weakness is extreme, saliva dribbles from the mouth, bed-sores and flexure-contractions may develop, the patient becomes entirely bedridden and coma and convulsions generally terminate the picture.

The classical picture of sleeping sickness described above represents that encountered in areas where the virulence of the trypanosome is high. Recent investigation has shown that in both East and West Africa many mild cases occur in which slight toxic features, such as headache and a little fever, are the only manifestations of the disease. Prolonged observation, however, reveals that symptoms are usually periodic and patients are frequently incapacitated temporarily. A stupid or sad appearance is often obvious, while early and slight facial asymmetry, hypotonia, insomnia, rheumatic-like pains, loss of strength and impotence are common (McLetchie). The mildness of the clinical symptom, however, may be very misleading for when a group of such cases was followed up by Kinghorn on the Gold Coast nearly half of them were dead within 13 months. It is the trypanosome of low virulence which causes epidemics. Lester classified strains of *T. gambiense* into three categories, (1) low virulence with high transmissibility producing mild symptoms, scanty blood infection and rarely proving trypanamide resistant, (2) medium virulence producing nervous symptoms in 6 to 12 months, (3) high virulence resembling *T. rhodesiense*, and feebly transmissible, liable to relapse after treatment and very resistant to trypanamide. Fortunately resistance to suramin appears to be rare.

Complications.—Intercurrent infections like dysentery and pneumonia often cause death, and abortion and still-births are not infrequent. Keratitis, iridocyclitis and choroiditis occur, and during treatment with trypanamide a careful watch has to be made for the onset of optic atrophy.

Diagnosis.—Irregular fevers, especially if associated with cervical adenitis, should arouse suspicion in patients who have been exposed to infection, and under such circumstances laboratory assistance is invaluable. Autoagglutination of the blood is frequently observed. Trypanosomes may be found in thin or in thick blood films, or in smears from centrifuged citrated blood. Even more satisfactory is the method of early gland puncture, provided the gland juice be aspirated in a dry syringe, when 87 per cent. of cases with adenitis show trypanosomes (Broden). Inoculation of white rats or guinea-pigs with blood or emulsified excised gland is also a very valuable procedure. Lumbar puncture is essential in later cases; typically the cerebrospinal fluid, which is often under increased pressure, shows an increase in globulin and lymphocytes, and later in medium-sized and vacuolated mononuclear cells as well. The advanced cases have counts of from 15 to 100 cells per c.mm.; trypanosomes are often difficult or impossible to demonstrate, even after centrifuging the fluid and animal inoculation. In relapses after suramin it is rare to find trypanosomes in gland juice or blood and here diagnosis must be made on clinical grounds or by lumbar puncture.

Treatment.—**PROPHYLACTIC**—The only permanent method of control is to eliminate man-fly contact wherever possible (Lester). Immediate control is achieved by chemotherapy-mass treatments of epidemics. Next comes anti-tsetse measures such as protective clearance of forest and bush around lakes, rivers, fords and water-points for the riverine species, and fly destruction by D D T sprayed from the air. Finally come administrative measures like concentration of the population, re settlement, improved dietary and general welfare.

Personal prophylaxis is important. White clothes are advised in tsetse country, shorts should not be worn and veils and gloves are used if feasible. Where possible travelling should be done at night.

Drug prophylaxis is also proving very valuable—especially in mining camps. Single injections of suramin (2 g) give protection for 6 weeks but not 3 months, as was previously thought. Pentamidine isethionate, 250 mg, given intramuscularly every 4 or 5 months appears to afford regular protection (McLetchie).

CURATIVE—Mass treatment of epidemics aims at the radical cure of individual sick patients, sterilising the carrier and rendering him physically fit. Several specific drugs are of proved value and the use of two drugs simultaneously is now generally advocated owing to synergic action.

(1) Suramin (Antrypol, Bayer 205, Germanin) is a complex organic urea compound, which is injected intravenously (10 g) at intervals of 2 or 3 days until a total of 100 g have been given. It is especially useful in sterilising the blood in early cases infected with *T. gambiense* or *T. nigriense* and has a prolonged prophylactic action. Sometimes toxic effects on the kidneys are found, and when possible the urine should be watched for albuminuria and casts.

(2) Tryparsamide (sodium N-phenylglycineamide p arsonate) is given intravenously at 5 to 7 days' interval in doses of 20 to 40 mg per kg (1.5 to 3.0 g for an adult) until a total dosage of 300 g have been administered. Children receive relatively larger doses. Tryparsamide is the only safe and effective drug in the advanced stages of sleeping sickness where the central nervous system has been involved, but owing to the frequency of resistant strains and its very moderate trypanocidal activity it should be given in conjunction with suramin or pentamidine isethionate for field use. Untoward symptoms are jaundice, exfoliative dermatitis and optic atrophy, the onset of which may be indicated by failing sight, contraction of the fields of vision, flashes of light, ocular pain, lacrimation and photophobia. The greater the changes in the cerebrospinal fluid, the greater the tendency to optic nerve degeneration, more often than not this complication is due to the disease rather than the drug. Where the nervous system has been involved it is not justifiable to conclude that cure has resulted until the cerebrospinal fluid has remained normal for 6 months, and when it is found to be abnormal after treatment another course should be given.

(3) Pentamidine isethionate is an aromatic diamidine compound which has marked trypanocidal properties and is valuable in the treatment of early cases of *T. gambiense*. It appears to be free from dangerous toxic effects and is non toxic in combination with tryparsamide, from this viewpoint it is most useful when patients are intolerant to suramin. It is very valuable as a prophylactic drug and appears to have some slight action in cases with involvement of the central nervous system. The drug is administered parenterally in a 10 per cent solution preferably as an intramuscular injection up to 2 to 4 mg per kg body weight, local discomfort may follow. If given intravenously the patient should receive 3 mg per kg body weight for 10 consecutive days, owing to possible depressor effects the patient should be recumbent and the injection given slowly, 3 minutes being taken.

Combined treatment—Owing to synergic action it is advisable for field use to give suramin or pentamidine in combination with tryparsamide. A mixture of 0.5 g of suramin and 1.5 g of tryparsamide is injected at intervals of 5 days. Eight

injections are given in early cases and 20 injections in advanced cases. An alternative treatment, and one specially valuable where patients are intolerant to suramin, consists of pentamidine isethionate 150 mg daily for 5 to 7 days, followed by a course of intravenous tryparsamide injections at 5 to 7 day intervals. The first dose of tryparsamide should be 1.0 g, succeeding doses 1.5 or 2.0 g. A course of 5 doses of tryparsamide is given in moderately severe cases, and up to 10 doses in advanced cases. The pentamidine may be given concurrently with the tryparsamide, provided that doses of the latter are given at the usual 5 to 7 day intervals (McLetchie). Whatever treatment is adopted the patient's general health must be budt up in every way and intercurrent disease eliminated.

SOUTH AMERICAN TRYPANOSOMIASIS

Synonyms—Chagas' Disease; Schizotrypanosomiasis

Definition—A disease occurring in parts of South America caused by the pleomorphic trypanosome, *Trypanosoma cruzi* (Chagas, 1909), which occurs both in the blood and in a Leishmanial stage in the myocardium, somatic muscle, brain and liver.

Ætiology.—The disease, which has been recorded in several states in Central and South America, affects children and occasionally adults of both sexes. *T. cruzi* is a short, broad trypanosome (20 μ long) with a central nucleus and large, ovoid, posteriorly situated kinetoplast. The disease is conveyed to man by certain reduviid bugs, of the genera *Triatoma*, *Rhodnius* and *Eratyrus*, which have imbibed trypanosomes during their meal of blood. After a developmental cycle of 6 to 15 days metacyclic trypanosomes are discharged in the excreta and infect man via lesions in the skin or mucous membranes. In Brazil the chief vector is *Triatoma meguta*. The trypanosomes are found in the peripheral blood only for a short time after infection, after which they assume a Leishmanial form within the cells of different organs where they undergo division, and from time to time pass back into the peripheral circulation. *T. cruzi* is a natural parasite of opossums and armadillos, and man is only occasionally and accidentally infected (Strong).

Pathology.—The Leishmanial forms are found especially in the heart, voluntary muscles, brain and liver, where they multiply, causing cell destruction, cellular infiltration, hyperplasia of connective tissue and fibrosis. The central nervous system shows lesions resembling meningo encephalomyelitis.

Symptoms.—The incubation period averages about 9 days, varying from 7 to 14 days. The acute stage occurs in infants under 1 year and is characterised by high fever of continuous type, unilateral conjunctivitis, facial œdema which may extend to the trunk and enlargement of the liver, spleen and lymphatic glands. Trypanosomes are demonstrable in the blood only during the fever. Death may occur from cardiac failure or with encephalo-meningitic symptoms due to parasitic involvement.

The chronic stage may supervene following the acute attack in children, or affect older children or adults. There may be irregular fever, anæmia, hepatomegaly, splenomegaly and adenitis, but trypanosomes are only found in the blood if the temperature be raised and then only with difficulty. Many of the symptoms previously attributed to this stage of the disease are now known to be due to endemic goitre with superadded infection with *T. cruzi*. Serious disturbances of heart rhythm and neurological manifestations with paralysis may result from local involvement of the myocardium or central nervous system.

Diagnosis.—In the early acute stages this is made by finding trypanosomes in fresh blood, in stained thick or thin films or in stained films prepared after centrifuging 5 to 10 ml of citrated blood. Occasionally puncture of the voluntary muscles may reveal the Leishmanial forms. Inoculation of guinea pigs is sometimes successful, and a reliable complement fixation reaction has been worked out by Machado and others, using extracts of heavily infected heart muscle or cultured trypanosomes.

Prognosis—The prognosis in acute cases, especially where the central nervous system or heart is involved, is grave.

Treatment—**PROPHYLACTIC**—Destruction of the reduviid bug vectors by chemical means, fumigation, etc., is necessary. Better houses and the use of mosquito nets are important factors in preventing infection.

CURATIVE—No specific treatment is available, the various drugs successful in African trypanosomiasis being ineffective.

AMŒBIASIS

1 Intestinal amœbiasis and amœbic dysentery

2 Amœbic hepatitis and liver abscess

Five forms of amœbæ may occur in human fæces, namely *Entamœba histolytica*, *Entamœba coli*, *Endolimax nana*, *Dientamœba fragilis* and *Iodamœba butschlii*. Of these only the first, *Entamœba histolytica*, is known with certainty to be pathogenic to man. One fatal case of amœbiasis in a Japanese prisoner-of-war was found by Derrick at necropsy to show amœbic ulceration of the colon and stomach and extensive amœbic involvement of the lungs and brain. Tissue sections all showed dense infection with a small amœba which Wenyon and Hoare could not differentiate in tissue section from *I. butschlii*. Unfortunately this amœba was never studied in the fæces so its identity remains doubtful. As it was not *E. histolytica*, the only alternatives are that it was a new amœba pathogenic to man or that under conditions which are not understood, *I. butschlii* can occasionally become virulently pathogenic and invade human tissues with fatal consequences. During the War of 1939–1945 amœbic infection was responsible for from 10 to 20 per cent of all cases of dysentery in the tropics, subtropics and Middle East, and was specially severe and prevalent in India and Burma. The problem created by the return of large numbers of infected troops to the United Kingdom was considerable, especially as a number of patients appeared to be infected with a strain or strains of *E. histolytica* which were relatively emetine resistant, and amœbic granulomas simulating malignant growths appeared to be no longer rare. Liver involvement has always been a frequent complication of amœbic infection of the colon, but owing to their clinical importance, intestinal amœbiasis and amœbic dysentery on the one hand and amœbic hepatitis and liver abscess on the other will be separately considered.

1 INTESTINAL AMŒBIASIS AND AMŒBIC DYSENTERY

Definition—Amœbic dysentery results from infection of the colon with *E. histolytica* (Schaudinn, 1903), and is generally characterised by an afebrile diarrhoea, several voluminous stools containing brownish mucus and dark red blood usually being passed daily. Latency is a marked feature, relapses are frequent, while amœbic hepatitis and liver abscess not infrequently supervene (p. 279).

Ætiology—This disease is widely distributed throughout the tropics and subtropics, but occasionally occurs in temperate regions. Both sexes and all ages are liable, though it is less common in young children. *E. histolytica* gains access to the body in its cystic form via the mouth in drinking water or food, especially vegetables, contaminated by convalescent or contact carriers, while flies either directly or indirectly may convey the infection. The cysts pass through the stomach intact, after which their walls are dissolved by the pancreatic juice, and the encysted amœbulae escape and ultimately invade the colonic mucosa. During this stage it is the large, actively motile, tissue-invading amœbæ (20 to 30 μ in diameter), containing ingested red blood cells which are present in faecal mucus, but later, as the lesions become quiescent and begin to heal pre-cystic amœbæ appear in the excreta, originating

superficially by binary fission from the more deeply situated tissue-invading forms. Preeystic amœbæ are much smaller (7 to 18 μ in diameter) less actively motile, contain no erythrocytes, and must be distinguished from *E. coli*. Different races of amœbæ give rise to cysts of different size containing one, two or four nuclei and the characteristic chromidial bodies, they are met with in the faeces of chronic cases and carriers.

Pathology—After passing into the glands of the large intestine, the tissue invading amœbæ multiply, cause toxic degeneration of the lining cells with blockage of the tubules and the production of slightly raised yellowish nodules (Wenyon). Simultaneously, the inter glandular connective tissues are invaded, and a toxic gelatinous necrosis is produced, characterised by an absence of polymorphonuclear leucocytes and occasionally by thrombosis of adjacent mesenteric venules. Small abscesses form which rupture, producing superficial ulcers with undermined edges. The process now extends through the *muscularis mucosæ* to the submucosa, larger bottle neck ulcers sometimes resulting which are often an inch or more in diameter and are filled with mucoid material, cell debris and amœba. The brown mucus and degenerated blood so characteristic of the amœboid stool originate in such lesions. Following rupture of the primary ulcer others are similarly produced, the maximum involvement being in the cæcum ascending and sigmoid colon which may be considerably thickened, and the rectum. Ulceration rarely extends above the ileo cæcal valve, and even in extensive colonic involvement the intervening mucosa does not generally appear inflamed. Frequently ulcers heal with pigmented scarring of the mucosa and thickening on the peritoneal surface, while in other instances ulceration extends to the muscular layers, adhesions may form, and more rarely sloughing and perforation may lead to a fatal peritonitis. Secondary bacterial invaders probably play a prominent rôle in the development of extensive ulcerative and gangrenous lesions of this type. Tumour-like amœbic granulomas known as amœbomas may involve the colon being situated especially at the sigmoid, splenic and hepatic flexures the rectum, mid-transverse colon and cæcum.

Rectal amœbomas may present as a wart like mass extending around the anal margin or internally appear as a firm grey mass with an ulcer crater which exudes dark or reddish brown thin pus containing vegetative *E. histolytica*. If amœbæ are not demonstrable in the exudate, a snipping removed during proctoscopy or sigmoidoscopy will enable a diagnosis to be made. An amœboma involving the cæcum or the ascending transverse or descending colon may produce a palpable tumour, show radiologically as a constrictive filling defect of the bowel and clinically produce features of colonic obstruction. If undiagnosed and operated on without anti amœbic treatment death may result.

Invasion of the mesenteric venules may produce so called hepatitis (miliary amœbic abscesses) or solitary or multiple amœbic abscesses of the liver, lung, brain and spleen the chief pathological feature of which is the presence of tissue invading amœbæ in their non fibrous necrotic walls.

Symptoms—The incubation period varies from 3 weeks to 3 months. The onset is generally insidious, commencing with an afebrile diarrhoea, later, three or four bulky, fetid stools containing brown mucus and degenerate blood may be passed daily. Occasionally the onset is acute, as in bacillary dysentery, with fever, pain, griping and purging associated with the frequent evacuation of bloody, brown mucoid stools containing *E. histolytica*, tenesmus occurs if the rectum be involved. As the condition progresses considerable weight is lost the skin may become dry and earthy brown and anorexia, dyspepsia, anaemia of secondary type and a mild neutrophil leucocytosis may develop. Examination often reveals thickening and tenderness of the colon especially of the cæcum and sigmoid. Tenderness and enlargement of the liver and abnormal physical signs at the base of the right lung should also be sought for. Sigmoidoscopy generally shows the typical amœbic lesions, in the early stages

small superficial yellowish nodules and petechial hæmorrhages may be noted, while later painless yellow ulcers surrounded by zones of hyperæmia appear, scrapings reveal large tissue invading *E. histolytica*. As a rule the intervening mucosa appears normal, but occasionally a generalised proctitis may be observed which completely clears up under emetine treatment.

Patients from the tropics may give no history of dysentery yet cysts of *E. histolytica* are found in the stools. In this group recurrent abdominal pain is sometimes complained of, and physical examination may reveal localised tenderness over the cæcum, the transverse colon or the sigmoid. Nausea, flatulence and constipation are common, and a few complain of dyspepsia and diarrhœa. Sigmoidoscopy reveals no abnormality. Appendicitis, cholecystitis, gastric or duodenal ulcer, gastritis or diverticulitis may be suspected, yet treatment with emetine-bismuth iodide which generally results in the disappearance of cysts from the fæces is not infrequently followed by the amelioration of gastro-intestinal symptoms and under such circumstances they can with reasonable justification be regarded as of amœbic origin. Many other cyst carriers from the tropics, however, complain of no symptoms whatever, and in the absence of a history of dysentery or recurrent diarrhœa it remains uncertain whether *E. histolytica* is living on bacteria in the lumen of the gut as a harmless commensal, or has invaded the bowel wall without producing macroscopic lesions and clinical symptoms. Such individuals constitute a potential source of danger to the community, may develop liver abscess later and are better treated once a definite laboratory diagnosis has been made.

Complications.—Post dysenteric adhesions, retro colic abscess, intestinal hæmorrhage and perforation with peritonitis may result by an extension of the ulcerative process. Perforations are not infrequently multiple, and are often associated with extensive gangrene of the bowel wall. The appendix has been found involved in 7 per cent of cases. Amœbic hepatitis and amœbic abscess are frequent complications and owing to their clinical importance are separately considered (pp 279-280). More rarely, amœbiasis of the lungs, brain, spleen, seminal vesicles and testicles has been recorded. Amœbic ulceration of the skin and subcutaneous tissues may develop around the sinus associated with a liver abscess, a colostomy wound or amœbic lesions involving the anus. Amœbiasis of the urinary tract is generally secondary, a colonic or rectal amœbic ulcer involving the bladder or a liver abscess rupturing into the pelvis of the kidney.

Course.—The majority of cases run a chronic course, and even without specific treatment the tendency for amœbic dysentery is to improve temporarily, but relapses are frequent and very characteristic of the disease. Latency is marked, and contact carriers are frequently encountered who never suffered from dysentery.

Diagnosis.—The diagnosis is made by finding the large tissue invading forms of *E. histolytica* in the fresh mucus in acute cases, and the precystic forms or cysts in the fæces of chronic cases and carriers. Scrapings obtained during sigmoidoscopy may reveal amœbæ despite previous negative reports on the fæces, and in any case of doubt instrumental examination should be carried out. Cytologically fewer pus cells are present in amœbic exudate than in bacillary dysentery, and Charcot-Leyden crystals also not infrequently occur. Radiographic examination after a barium enema eliminates many other lesions entering into the differential diagnosis, while in distinguishing malignant disease, chronic bacillary dysentery, ulcerative colitis, bilharzial and balantidial ulcerations of the colon from chronic amœbiasis and amœboma sigmoidoscopy, reinforced by laboratory methods of examination, becomes indispensable. A complement fixation reaction has been perfected by Craig using an alcoholic extract of cultures of *E. histolytica* as antigen but the test is not yet suited for routine diagnosis.

Prognosis.—With modern methods of treatment uncomplicated cases of amœbic dysentery almost invariably recover, and a large proportion are permanently curable. The prognosis is naturally more serious where complications like amœboma or liver

abscess exist Colonic perforation with peritonitis is frequently, and brain abscess almost invariably, fatal

Treatment.—**PROPHYLACTIC**—As the disease is acquired by faecal contamination of food and water, it becomes important to ascertain that personal servants and cooks are not carriers Food should be protected from flies, and measures should be taken to avoid contamination of water and uncooked vegetables

CURATIVE—Long before amœbic and bacillary dysentery were differentiated, ipecacuanha was recognised as effective in certain cases Later, one of its alkaloids, emetine, was proved of great value by Rogers in India, and more recently other preparations, including bismuth emetine-iodide, emetine periodide and auremetine, have been introduced The toxic properties of emetine and its compounds should never be forgotten, and during intensive treatment it is essential that the patient be kept in bed on a simple, non-irritating, low-residue diet, milk being citrated to avoid clot formation

Emetine is indicated where the tissue-invading amœbæ have produced visceral complications like hepatitis and amœbic abscess, and also early during the acute primary attack. Emetine hydrochloride is injected intramuscularly or subcutaneously in 1-grain doses daily for a period not exceeding 10 days in a normal-sized adult, but the dose should be decreased in debilitated persons and those of low body weight Children receive a dose proportional to age, for those under 3 years never exceeding $\frac{1}{4}$ grain, and for those under 6 years $\frac{1}{2}$ grain per day. Emetine is a muscle poison and, owing to the cumulative action of the drug, treatment should not be repeated within 2 to 3 weeks Diarrhœa is commonly induced, and toxic symptoms include asthenia, cardio-vascular depression, low blood pressure, tachycardia, extrasystoles, extreme muscular weakness causing paresis or even paralysis of the limbs; death may occur from cardiac failure, with paroxysmal tachycardia or auricular fibrillation

Emetine-Bismuth-Iodide (E B I) —This drug is preferable to emetine hydrochloride in chronic cases and carriers showing cysts, but it has the disadvantage of causing considerable nausea and vomiting, and is best given on an empty stomach late at night in specially coated tablets (B. W. & Co.) or in gelatine capsules, 4 hours after the last feed Phenobarbitone (gr 1) is given half an hour previously when necessary Nightly doses, of gr. 3, are given for 10 to 12 doses, the total course varying from gr. 30 to 36 During the course patients often lose weight, and usually there is a fall in blood pressure and slowing of the pulse

Carbarsone, which is a pentavalent arsenical, is a moderately effective amœbicicide in intestinal infections acting on both the cyst and vegetative forms, but the proportion of radical cures achieved is not high It is of no value in hepatitis, liver abscess or other visceral complications The drug is administered in tablets containing 0.25 g., one being given twice daily after food for 10 days

Chiniofon—Chiniofon (Yatren) is sodium iodo-oxyquinoline-sulphonate, and can be given by the mouth or as a retention enema The adult dose is $\frac{1}{2}$ to 1 g. of the powder in gelatine capsules thrice daily for 10 days, repeated if necessary after a week's interval If given *per rectum* the bowel should be first washed out with 1 pint of 2 per cent sodium bicarbonate solution to remove mucus, and an hour later 200 ml. of a 2.5 per cent solution of chiniofon is run into the rectum and retained for as long as 8 hours if possible Two somewhat similar preparations, Vioform (40 per cent iodine) and Diodoquin (60 per cent iodine) are widely used for oral treatment, but are too irritant for rectal use Diodoquin is available in tablet form (0.2 g.) the standard course consisting of 2 tablets thrice daily after food for 3 weeks In intractable emetine-resistant cases this dosage may be doubled

Combined treatment—An effective combination in chronic relapsing amœbiasis and cyst cases consists of a 10-day course of retention enemas of chiniofon in the morning and E. B. I. at night, followed by a 10-day course of carbarsone During the latter period a liberal diet reinforced with vitamins is advisable Prior to the war

this treatment almost invariably resulted in clinical cure and gave a radical cure rate approximating to 90 per cent. In Burma and India during the war amœbic dysentery was especially severe and prevalent, and a number of patients returning to England were found to relapse repeatedly despite combined treatment of this type. Hargreaves stressed the importance of secondary bacterial infection in severe refractory cases and advocated the additional use of penicillin combined with sulphaguanidine or succinylsulphathiazole as a life-saving measure in such patients. Though almost all patients with chronic relapsing amœbiasis are curable, exceptional ones are encountered who fail to respond even to massive doses of penicillin, sulphonamides, emetine, emetine bismuth-iodide and other amœbicidal drugs, they occasionally die with vegetative amœbæ which appear resistant to all known forms of treatment. Amœboma, liver abscess or other complications are, however, almost invariably present in such patients. It has not yet been determined how far this failure to respond to treatment is dependent on (1) the strain of *E. histolytica* being resistant to emetine, (2) inability of the drug to reach inaccessibly situated amœbæ in effective concentration or (3) the presence of secondary bacterial infection. Penicillin and the sulphonamides are of value only in the presence of those relatively rare superadded infections with bacteria sensitive to these drugs, there is no evidence that they enhance the specific amœbicidal properties of emetine in uncomplicated refractory cases.

Antibiotics—Adams recommends chlortetracycline or oxytetracycline orally 0.5 g 6 hourly for 10 days. Parasites disappear from stools after 3 or 4 days of treatment. Some cases may relapse but a high proportion of both symptomatic and asymptomatic cases are sterilised. Antibiotics given in conjunction with amœbicidal drugs may be even more effective.

Surgical treatment—Amœbomas generally respond to anti-amœbic drug treatment but occasionally surgical excision is necessary to establish radical cure. Perforation of the colon demands immediate laparotomy, large areas of the bowel may be gangrenous, more than one ulcer often sloughs through and thus complication is generally fatal. Patients with amœbic brain abscesses almost invariably die despite surgical intervention. The treatment of liver abscess and its complications are dealt with in detail in the section that follows.

For BACILLARY DYSENTERY, see p. 112

2 AMOEBC HEPATITIS AND LIVER ABSCESS

Ætiology—Amœbic hepatitis and liver abscess are invariably secondary to a primary infection of the colon with the tissue invading amœba, *E. histolytica*. Amœbic dysentery may precede the onset of hepatic symptoms by weeks, months or years. In others there may be a history of attacks of diarrhœa without blood or mucus, while some patients cannot recollect any intestinal disturbance whatever. The stools frequently do not contain the cystic or vegetative forms of *E. histolytica* in demonstrable numbers at the time when hepatic symptoms appear. Liver abscess may develop within 3 months of the primary intestinal infection or be delayed for as long as 40 years after leaving an endemic area.

Pathology.—In amœbic hepatitis, amœbæ reach the liver via the portal vein in small emboli containing *E. histolytica* derived from the thrombosed veins draining submucous ulcers in the colon. Small intrahepatic portal thromboses and infarctions result and cytolytic enzymes from the amœbæ lead to peptonisation of the necrosed areas. The great mass of hepatic cells between amœbic foci are unaffected, and in so called amœbic hepatitis liver function tests reveal little, if any, abnormality.

Liver abscesses are formed by fusion of a number of these small adjacent foci. The walls of the abscess are lined by a shaggy necrotic zone of hepatic tissue, and, deeper in, vegetative *E. histolytica* are found. A fibrous tissue capsule probably, only

abscess exist. Colonic perforation with peritonitis is frequently, and brain abscess almost invariably, fatal.

Treatment.—**PROPHYLACTIC.**—As the disease is acquired by faecal contamination of food and water, it becomes important to ascertain that personal servants and cooks are not carriers. Food should be protected from flies, and measures should be taken to avoid contamination of water and uncooked vegetables.

CURATIVE.—Long before amœbic and bacillary dysentery were differentiated, ipecacuanha was recognised as effective in certain cases. Later, one of its alkaloids, emetine, was proved of great value by Rogers in India, and more recently other preparations, including bismuth-emetine-iodide, emetine periodide and auremetine, have been introduced. The toxic properties of emetine and its compounds should never be forgotten, and during intensive treatment it is essential that the patient be kept in bed on a simple, non-irritating, low-residue diet, milk being citrated to avoid clot formation.

Emetine is indicated where the tissue-invading amœbæ have produced visceral complications like hepatitis and amœbic abscess, and also early during the acute primary attack. Emetine hydrochloride is injected intramuscularly or subcutaneously in 1-grain doses daily for a period not exceeding 10 days in a normal-sized adult, but the dose should be decreased in debilitated persons and those of low body weight. Children receive a dose proportional to age, for those under 3 years never exceeding $\frac{1}{8}$ grain, and for those under 6 years $\frac{1}{4}$ grain per day. Emetine is a muscle poison and, owing to the cumulative action of the drug, treatment should not be repeated within 2 to 3 weeks. Diarrhœa is commonly induced, and toxic symptoms include asthenia, cardio-vascular depression, low blood pressure, tachycardia, extrasystoles, extreme muscular weakness causing paresis or even paralysis of the limbs; death may occur from cardiac failure, with paroxysmal tachycardia or auricular fibrillation.

Emetine-Bismuth-Iodide (E.B.I.).—This drug is preferable to emetine hydrochloride in chronic cases and carriers showing cysts, but it has the disadvantage of causing considerable nausea and vomiting, and is best given on an empty stomach late at night in specially coated tablets (B. W. & Co.) or in gelatine capsules, 4 hours after the last feed. Phenobarbitone (gr. 1) is given half an hour previously when necessary. Nightly doses, of gr. 3, are given for 10 to 12 doses, the total course varying from gr. 30 to 36. During the course patients often lose weight, and usually there is a fall in blood pressure and slowing of the pulse.

Carbarsone, which is a pentavalent arsenical, is a moderately effective amœbicide in intestinal infections acting on both the cyst and vegetative forms, but the proportion of radical cures achieved is not high. It is of no value in hepatitis, liver abscess or other visceral complications. The drug is administered in tablets containing 0.25 g., one being given twice daily after food for 10 days.

Chinofon.—Chinofon (Yatren) is sodium iodo-oxyquinoline-sulphonate, and can be given by the mouth or as a retention enema. The adult dose is $\frac{1}{2}$ to 1 g. of the powder in gelatine capsules thrice daily for 10 days, repeated if necessary after a week's interval. If given *per rectum* the bowel should be first washed out with 1 pint of 2 per cent. sodium bicarbonate solution to remove mucus, and an hour later 200 ml. of a 2.5 per cent. solution of chinofon is run into the rectum and retained for as long as 8 hours if possible. Two somewhat similar preparations, Vioform (40 per cent. iodine) and Diodoquin (60 per cent. iodine) are widely used for oral treatment, but are too irritant for rectal use. Diodoquin is available in tablet form (0.2 g.), the standard course consisting of 2 tablets thrice daily after food for 3 weeks. In intractable emetine-resistant cases this dosage may be doubled.

Combined treatment.—An effective combination in chronic relapsing amœbiasis and cyst cases consists of a 10-day course of retention enemas of chinofon in the morning and E.B.I. at night, followed by a 10-day course of carbarsone. During the latter period a liberal diet reinforced with vitamins is advisable. Prior to the war

this treatment almost invariably resulted in clinical cure and gave a radical cure rate approximating to 90 per cent. In Burma and India during the war amoebic dysentery was especially severe and prevalent, and a number of patients returning to England were found to relapse repeatedly despite combined treatment of this type. Hargreaves stressed the importance of secondary bacterial infection in severe refractory cases and advocated the additional use of penicillin combined with sulphaguanidine or succinylsulphathiazole as a life saving measure in such patients. Though almost all patients with chronic relapsing amoebiasis are curable, exceptional ones are encountered who fail to respond even to massive doses of penicillin, sulphonamides, emetine, emetine bismuth iodide and other amoebicidal drugs, they occasionally die with vegetative amoebae which appear resistant to all known forms of treatment. Amœboma, liver abscess or other complications are, however, almost invariably present in such patients. It has not yet been determined how far this failure to respond to treatment is dependent on (1) the strain of *E. histolytica* being resistant to emetine, (2) inability of the drug to reach inaccessibly situated amoebae in effective concentration or (3) the presence of secondary bacterial infection. Penicillin and the sulphonamides are of value only in the presence of those relatively rare superadded infections with bacteria sensitive to these drugs, there is no evidence that they enhance the specific amoebicidal properties of emetine in uncomplicated refractory cases.

Antibiotics—Adams recommends chlortetracycline or oxytetracycline orally 0.5 g 6 hourly for 10 days. Parasites disappear from stools after 3 or 4 days of treatment. Some cases may relapse but a high proportion of both symptomatic and asymptomatic cases are sterilised. Antibiotics given in conjunction with amoebicidal drugs may be even more effective.

Surgical treatment—Amœbomas generally respond to anti amoebic drug treatment but occasionally surgical excision is necessary to establish radical cure. Perforation of the colon demands immediate laparotomy, large areas of the bowel may be gangrenous, more than one ulcer often sloughs through and this complication is generally fatal. Patients with amoebic brain abscesses almost invariably die despite surgical intervention. The treatment of liver abscess and its complications are dealt with in detail in the section that follows.

For BACILLARY DYSENTERY, see p. 112

2 AMOEBC HEPATITIS AND LIVER ABSCESS

Ætiology—Amoebic hepatitis and liver abscess are invariably secondary to a primary infection of the colon with the tissue invading amoeba *E. histolytica*. Amoebic dysentery may precede the onset of hepatic symptoms by weeks, months or years. In others there may be a history of attacks of diarrhoea without blood or mucus while some patients cannot recollect any intestinal disturbance whatever. The stools frequently do not contain the cystic or vegetative forms of *E. histolytica* in demonstrable numbers at the time when hepatic symptoms appear. Liver abscess may develop within 3 months of the primary intestinal infection or be delayed for as long as 40 years after leaving an endemic area.

Pathology—In amoebic hepatitis, amoebae reach the liver via the portal vein in small emboli containing *E. histolytica* derived from the thrombosed veins draining submucous ulcers in the colon. Small intrahepatic portal thromboses and infarctions result and cytolytic enzymes from the amoebae lead to peptonisation of the necrosed areas. The great mass of hepatic cells between amoebic foci are unaffected, and in so called amoebic hepatitis liver function tests reveal little if any abnormality.

Liver abscesses are formed by fusion of a number of these small adjacent foci. The walls of the abscess are lined by a shaggy necrotic zone of hepatic tissue, and, deeper in, vegetative *E. histolytica* are found. A fibrous tissue capsule probably only

forms in the presence of secondary bacterial infection and this is especially marked where the abscess cavity has been drained. The commonest site for liver abscess is the superior surface of the liver on the right side. Some 80 per cent. of liver abscesses are located in the right half of the liver, 10 per cent. in the left half and 10 per cent. in both. The predominant right-sided distribution is due to streamline effects in the portal vein, the blood from the superior mesenteric vein being thereby diverted to the right branch and that of the inferior mesenteric to the left branch of the portal vein. In fatal cases of liver abscess in Indians, Rogers found 66.6 per cent. of the intestinal lesions were limited to the cæcum and ascending colon; blood from here drains into the superior mesenteric vein—hence the frequency of right-sided amœbic abscesses of the liver. A large destructive abscess involving one half of the liver leads to compensatory hypertrophy of the other half. When an amœbic abscess reaches the surface adhesions are formed with adjacent structures and pointing and rupture may follow. In uncomplicated cases the pus is chocolate coloured or resembles anchovy sauce and microscopical examination reveals necrosed liver cells, degenerating leucocytes, red blood corpuscles and fat droplets. Large motile *E. histolytica* containing ingested red blood corpuscles appear later, though they are not evident at first in the aspirated material. In the 15 per cent. of cases in which secondary bacterial infection has ensued, creamy-yellow or greenish-yellow pus is found containing abundant polymorphonuclear leucocytes: culture reveals the identity of the secondary invaders. These include streptococci, pneumococci, *Bact. coli*, *Ps. pyocyanea*, *Staphylococcus aureus*, *Cl. welchii* and other anaerobes.

Of the liver abscesses that rupture, over 50 per cent. do so into the lungs, pleural cavity or pericardium, 25 per cent. rupture into the peritoneal cavity and the remainder into adjacent structures such as the transverse colon, stomach, intestines, vena cava and kidneys. Rupture rarely occurs into a bile duct.

Symptoms.—The clinical picture in hepatic amœbiasis depends on whether the hepatitis has gone on to frank abscess formation or not. Generally only one abscess is present but two, three or even four may be found.

AMŒBIC HEPATITIS

This condition generally commences insidiously with irregular or remittent fever and sweating and these may be the only obvious clinical features for weeks. Generally, however, the liver is demonstrably enlarged and tender, while anorexia, hepatic pain, tenderness and epigastric discomfort sooner or later develop. Jaundice is rare. There is often a mild degree of leucocytosis with slight increase in the neutrophil polymorphonuclear leucocytes. The temperature generally responds within 3 days to emetine treatment and in cases of doubt therapeutic trial is justified even though the stools contain no *E. histolytica*.

AMŒBIC ABSCESS

The preliminary symptoms are similar to those described above. As the condition progresses intermittent fever may result associated with progressive deterioration of health, loss of weight and energy, lassitude, a dirty coated tongue, flatulent dyspepsia and bowel irregularity. Nervous irritability and sleeplessness follow. The complexion may be sallow and a moderate anaemia sometimes develops. Localising features depend on the site and size of the abscess.

(1) *Right half of the liver*—If the abscess is situated in the upper right half of the liver it tends to produce pressure on the diaphragm causing referred pain to the right shoulder and a dry cough (tussis hepatica). Physical signs such as diminished breath sounds, dullness and crepitations are often present at the base of the right lung. This condition is generally not due to direct amœbic involvement of the lung but

results from immobility of the diaphragm occasioned by an adjacent liver abscess which leads to defective ventilation, air absorption, pulmonary collapse and possibly secondary bacterial infection with pneumonia may follow. If the abscess points through the diaphragm it may rupture into the pleural cavity or into the lung when a pulmonary abscess with or without hæmoptysis may be produced. If the abscess opens into a bronchus, large quantities of pus resembling anchovy sauce may be coughed up and this may result in cure provided emetine be given. Amœbic abscess involving the lower right half of the liver and its inferior surface is less common and is associated with marked downward enlargement, localised or generalised tenderness along the edge of the liver and rigidity of the right rectus and adjacent muscles. Occasionally a localised area of tenderness may be demonstrable on the anterior surface of the liver. Sometimes pain may be referred to the right iliac fossa, and there may be associated tenderness over the cæcum due to amœbic ulceration. In some instances the abscess may bulge into the right loin space, simulating a renal condition. At times pain may first manifest itself at night during sudden movements or a feeling of weight may be felt when walking, the patient may hold his right arm and forearm to the side to splint the liver and for the same reason he not uncommonly sleeps on the right side. In large abscesses there may be bulging on the right side, widening of the intercostal spaces and restricted movement. In doubtful cases the chest should be measured to determine unilateral enlargement. Localised tenderness and œdema of the chest wall may indicate the site for exploratory puncture.

(2) *Left half of the liver*—An amœbic abscess in the left half of the liver may simulate gastric conditions owing to pressure on the stomach. Not infrequently the abscess presents in the epigastrium, and tenderness and rigidity of the left rectus are evident, later, redness, œdema, bulging and even fluctuation may be demonstrable in advanced cases. Rupture may occur into the stomach, pericardium, the base of the left lung or the left pleural cavity.

Special investigations—As a rule the stool presents no naked eye abnormalities, but mucus and blood may be present. Microscopical investigation may reveal vegetative forms of *E. histolytica* or more frequently amœbic cysts. Three specimens of stool should be examined, at least one being collected after a saline aperient. Repeated negative stool examinations do not, however, exclude hepatic amœbiasis.

Sigmoidoscopy may reveal scattered amœbic ulcers, and rarely an amœboma or an amœbic proctitis. The lesion should then be gently curetted and the scrapings examined microscopically for *E. histolytica* without delay. Usually, however, the mucosa presents a normal appearance.

In uncomplicated cases of amœbic hepatitis or abscess there is generally a leucocytosis of 10 000 to 20 000 leucocytes per c mm with a differential count of 65 to 80 per cent neutrophil polymorphonuclear leucocytes. When secondary bacterial infection ensues the total count generally rises above 20 000 leucocytes per c mm while the neutrophils constitute 80 to 90 per cent in the differential count.

Radiological investigation is of special value owing to the frequent pressure of the liver abscess exerted on the diaphragm. Elevation and diminished movement or "splinting" of the right cupola of the diaphragm is frequently present. Later "humping" of the diaphragm indicates the abscess is pointing towards the lung. Abnormal shadows at the base of the right or left lung may be due to pulmonary collapse, pneumonia, pulmonary amœbic abscess or pleural effusion. Sometimes an area of increased density in the liver indicates the site of the abscess. Left lobe abscesses are difficult to demonstrate, though they may produce characteristic pressure deformities on the barium-filled stomach (Miles).

Complications—The most fatal complications include rupture above or below the diaphragm and secondary bacterial infection. Jaundice is not common but does occur. Hæmatemesis is rare.

Diagnosis—Liver abscess is not infrequently diagnosed as basal pneumonia or

pleurisy with effusion, it may simulate suppurating hydatid cyst of the liver, sub phrenic abscess or perinephric abscess, all of which tend to implicate the pleural cavity or base of the lung via the diaphragm. It is sometimes confused with bilharzia cirrhosis especially when associated with bilharzia dysentery (*S. mansoni* and *S. japonicum*), suppurating pyelophlebitis, cholecystitis, septic cholangitis especially complicating *Clonorchis sinensis* infestation, malaria hepatitis and carcinoma of the liver with primary involvement of the colon. In diagnosis the history of exposure to infection in an endemic area or of definite amœbic dysentery, an intermittent or remittent temperature associated with an enlarged tender liver, leucocytosis and physical signs at the base of the right lung are important features. Immobility, elevation and "hump ing" of the diaphragm are characteristic radiological features. The finding of "anchovy sauce" pus during aspiration of the abscess is pathognomonic though it may take 48 hours before motile *E. histolytica* appear. The dramatic fall in temperature within 72 hours of commencing emetine injections favours an amœbic origin though occasionally it takes 5 days before the temperature reaches normal. The presence of cysts or vegetative forms of *E. histolytica* in the stools is presumptive evidence that the hepatomegaly has an amœbic origin, but in many instances sigmoidoscopy and repeated examination of the stools show no evidence of intestinal amœbiasis. At least 25 per cent of patients give no history of previous dysentery or diarrhoea.

Prognosis—Where the diagnosis is made early and appropriate treatment is adopted the prognosis is almost invariably good. The presence of multiple abscesses of the liver or of such complications as rupture or secondary bacterial infection increase the gravity of the condition. Open operation and drainage carries with it the risk of superadded bacterial contamination, and should only be undertaken if secondary bacterial infection has already occurred.

Treatment—*Emetine*—Amœbic hepatitis and even small amœbic abscesses generally respond rapidly to injections of emetine—grains 1 daily for 12 days. Provided secondary bacterial infection be absent pain and discomfort rapidly lessen the temperature falls to normal in about 3 to 5 days, and the leucocytosis decreases when there is anaemia due to amœbic infection a reticulocytosis follows about the seventh day. If relapse is to be avoided, the course of emetine injections should be followed by a course of emetine-bismuth iodide (3 grains nightly for 12 days) combined with chiniofon or other amœbicidal drugs to eradicate latent colonic infection. Owing to the cumulative action of emetine it is advisable to allow 2 or 3 weeks between the two courses of treatment. Where a large amœbic abscess has formed aspiration in addition to emetine therapy is advisable, but it should be postponed until the hepatic congestion has been relieved by several injections of emetine (Rogers).

Chloroquine diphosphate (Aralen) is a 4-amino-quinoline derivative which is amœbicidal and selectively stored in the liver in great concentration. Each tablet contains 0.25 g of the salt (=0.15 g base) and the course consists of 4 tablets daily for the first 2 days and 2 tablets daily for the next 14 to 19 days (Loeb). Conan Adams recommends a shorter course of 10 g of the salt daily for 6 days followed by treatment of the gut infection. This drug exerts a remarkable amœbicidal effect in hepatic amœbiasis, but its action on vegetative and cyst forms of *E. histolytica* in the colon is much weaker. Chloroquine is of special use in those rare cases of hepatic amœbiasis failing to respond satisfactorily to emetine and emetine-bismuth iodide therapy, but here a full course of treatment as recommended on page 2 may prove necessary in addition in order to eradicate the associated amœbic infection in the colon.

Aspiration—Owing to the viscosity of amœbic pus an exploratory needle of fair sized calibre must be used and it should not be inserted more than 3½ in. owing to the risk of perforating the inferior vena cava. During exploratory puncture continuous aspiration should be maintained by means of a large syringe or a Potain aspirator. If there is local tenderness, redness, œdema or bulging, the liver should

be explored over this site. In the absence of localising features the liver should be systematically examined commencing by inserting the needle inwards, backwards and slightly upwards in the eighth or ninth intercostal space in the right anterior axillary line. Several exploratory punctures may be necessary before pus is obtained. An average liver abscess contains about 2 pints of pus, but as much as 6 pints may be aspirated. The operation may be performed under general or local anaesthesia. Generally one aspiration suffices provided it is preceded and followed by adequate emetine treatment, but sometimes fever and leucocytosis persist or recur, the abscess cavity refills and repeated aspirations may prove necessary.

Open operation with or without drainage—Where an uncomplicated abscess involves the inferior surface of the right or left lobe of the liver, laparotomy may be necessary but the pus from such an abscess should be aspirated, and the wound closed without drainage unless bacterial infection be present. Practically the only indication for incision and drainage of an amœbic abscess is secondary bacterial infection and here penicillin, sulphonamides or streptomycin may prove of great value depending on the sensitivity of the secondary invaders to these different drugs. If an hepatic abscess ruptures into the lung, an hepatico-bronchial fistula may form and the pus be completely coughed up, treatment with emetine and postural drainage is generally effective. Should the abscess burst into the pleural cavity, empyema is likely to follow, aspiration and emetine injections should suffice unless there be secondary bacterial infection when drainage is necessary. Rupture into the peritoneal cavity is very serious, localised or generalised peritonitis resulting, immediate laparotomy is essential.

When it is necessary to drain a liver abscess the transpleural and the transperitoneal route should be avoided if possible. Where feasible the twelfth rib should be resected posteriorly and an extra serous route be adopted (Ochsner and Debaeky). When a transpleural approach is essential, a two stage operation should be carried out. Occasionally, where an amœbic abscess has been drained the sinus continues to discharge pus containing vegetative *E. histolytica* despite intensive courses of treatment with emetine, emetine bismuth iodide and Diodoquin reinforced with sulphonamides, penicillin and streptomycin to combat secondary bacterial infection. Under such circumstances, an intensive course of chloroquine may produce healing of the sinus and radical cure where all other drugs have failed.

CILIATE DYSENTERY

Definition—An ulcerative condition of the colon caused by *Balantidium coli* (Malmstren, 1857).

Ætiology—Human infections generally occur amongst those having occupational contact with pigs, which also harbour this ciliate, cases have been reported from Europe, America, Asia and Africa. The ciliate is egg shaped, 50 to 80 μ long by 30 to 55 μ broad, large and smaller forms are described. At its anterior end is the peristome, its interior contains a sausage shaped macronucleus, a micronucleus and vacuoles, while externally the whole body is covered with longitudinal rows of cilia. Encysted forms, 50 to 60 μ long, also occur in the feces. As healthy carriers are frequently encountered, it is possible that there is some secondary bacterial or other factor which determines the pathogenicity of *B. coli*.

Pathology—The colon and more rarely the ileum, shows ulcers distinguishable from amœbic lesions only by the demonstration of *B. coli*, which is found both in the cavity of the ulcer and the surrounding submucosa, it may also invade adjacent lymph glands, but not the liver.

Symptoms—In many cases the disease remains latent and symptoms are absent. In others the onset is insidious, with loose motions, later followed by sanguineous,

mucoid stools typical of chronic dysentery, anæmia may develop Intestinal perforation has been reported but never liver abscess

Diagnosis—Sigmoidoscopy may show colonic ulcers but diagnosis is dependent on demonstrating *B. coli* or its cysts in the excreta or in scrapings from the ulcers themselves

Prognosis—The mortality rate including latent cases is about 7 per cent. (Walker) but in those showing active dysentery it may reach 29 per cent. (Strong)

Treatment—Most of the remedies tried have not been satisfactory Agular advises restricting carbohydrates and increasing protein and fresh vegetables Stovarsol in doses of 0.25 g (4 grains) twice daily after meals for 1 week or carbarsone in a similar dosage for 10 days holds out some prospect of cure High colonic irrigation with solutions of iodine quinine and silver nitrate have been recommended but owing to the spontaneous disappearance of the ciliates from time to time the value of different remedies is difficult to assess

FLAGELLATE DIARRHŒA

There are three common intestinal flagellates of man *Giardia intestinalis* (Lambl 1859) which inhabits the upper intestine *Trichomonas hominis* (Lavaine, 1860) and *Chilomastix mesnili* (Wenyon 1910) found in the cæcum and colon Considerable controversy has arisen regarding their pathogenicity and though admittedly they are more common in cases of diarrhœa than in healthy individuals nowhere do they actually invade the intestinal mucosa Encysted flagellates are frequently found in normal stools and Dobell has pointed out that the free flagellate forms which are naturally adapted to a fluid medium only appear when the stools become liquid and loose From a clinical viewpoint, however *G. intestinalis* has some claim to pathogenicity

GIARDIA INTESTINALIS (Lambl, 1859)

Synonyms—*Lamblia intestinalis*, *Giardia lamblia*

Ætiology—This parasite inhabits the jejunum and duodenum and occasionally reaches the bile ducts It is a pear shaped flagellate (10 to 18 μ long \times 5 to 10 μ broad) possessing a concave sucker on its ventral surface and in the encysted form may persist for many years in the faeces As with certain other flagellates decreased or absent secretion of hydrochloric acid in the stomach appears to predispose to infection and after gastro jejunostomy they may be found in aspirated gastric juice

Pathology—In animals the glands of the small intestine may be found packed with giardia and though they never cause ulceration or hæmorrhage hyperinfection may lead to surface irritation (Wenyon) It is possible that in this fashion catarrhal enteritis results

Symptoms—Though encysted forms are often found in the faeces in healthy individuals periodic attacks of diarrhœa may occur associated with the passage of large quantities of clear mucus or ochre yellow stools in which enormous numbers of free flagellates occur The demonstration of these flagellates in the bile by means of a duodenal tube does not constitute evidence of pathological invasion of the biliary passages and gall bladder and the present tendency to attribute all manner of symptoms to giardia infection is to be deprecated

Prognosis—This is good fatal cases in man are unknown

Treatment—Mepacrine hydrochloride (Atebrin) in a dosage of 0.1 g t.d.s p.c. or a period of 7 days eradicates giardia infection permanently in some instances but relapses occur

F. RICKETTSIA DISEASES

INTRODUCTION

Rickettsiae are small, non-motile, Gram negative bodies usually less than 0.5μ in diameter which stain well by Giemsa's method. They are more or less pleomorphic, and are found in both host tissues and arthropod vectors. They are cultivated in the yolk sac of the developing chick or in agar tissue culture, and suspensions can also be obtained from the lungs of infected rats and mice. In tissue they are mainly located within mesothelial cells, either in the cytoplasm or the nucleus. Ricketts (1909) first noted these bodies in guinea-pigs and monkeys with Rocky Mountain spotted fever, and since then several varieties affecting man have been described. Thus, classical louse typhus is caused by *Rickettsia prowazeki*, murine or flea typhus by *R. mooseri*, Rocky Mountain exanthematic spotted fever by *Rickettsia* or *Dermacentroxenus rickettsi*, tsutsugamushi disease by *R. orientalis*, trench fever by *R. quintana*, and "Q" fever by *R. burneti*.

An ever-increasing number of typhus like fevers is being described in different parts of the world caused by rickettsiae, and carried by arthropods like lice, fleas, ticks and mites in which rodents play an important role as reservoirs of infection. They have been classified on a geographical basis, according to their insect vectors, or in terms of their agglutination reaction with OX2, OX19 and OXK strains of *Proteus vulgaris*.

Rickettsiae possess heat-labile and heat stable antigens, and sera from typhus patients contain or may contain the two corresponding types of antibody. Complement fixation reactions are of specific value in the diagnosis of epidemic typhus, murine typhus, Rocky Mountain spotted fever and "Q" fever.

The Weil-Felix Reaction—This reaction is due to the production by certain rickettsiae of non-specific agglutinins against the "O" non motile variant of certain strains of *Proteus* X. Suspensions of OX19, OX2 and OXK strains are employed.

Originally the reaction was carried out with living suspensions, but now the alcoholic method, which destroys the flagella and preserves solutions of "O" antigen is used. In general it may be said that OX19 is the main antigen for louse and flea-borne typhus, OXK for mite typhus, while the sera from patients with tick typhus, as a rule, react in low titre to all three strains. Felix thinks the strain forming the main antigen for the tick borne group has yet to be discovered. The serum from patients with "Q" fever or trench fever does not react with any of these strains.

For clinical purposes, a rising titre exceeding 1 in 125 may be taken as diagnostic. The test should be made as early as possible in order to estimate subsequent rises in titre. A significant rise is generally well established by the tenth day. The usual maximum titre of 1/1000 to 1/5000 may not be attained until convalescence, after which the reaction weakens and gradually becomes negative. Exceptionally, a maximum titre of 1/100,000 is attained.

Though the Weil-Felix reaction is of little diagnostic utility during the first week except in louse typhus, and may occasionally fail to reveal agglutinin in significant titre in severe cases until convalescence is reached, it is a reliable test of very real clinical value. Non specific stimulation of the proteus "O" agglutinin in other bacterial infections of man has been observed in tularaemia, chronic brucellosis, typhoid fever and infections with *Proteus vulgaris*, progressive rises in titre during the course of these diseases, however, do not occur.

The modified table on page 286, published by the Army Pathology Laboratory Service (1941), summarises data regarding the Rickettsial diseases affecting man.

DISEASE	RICKETTSIA	GEOGRAPHICAL DISTRIBUTION	INSECT VECTORS	POSSIBLE VERTEBRATE RESERVOIRS
Exanthematic typhus	<i>Rickettsia prowazeki</i>	Europe Abyssinia, North Africa, Belgian Congo, Asia Minor, Persia, North China, Mexico	Louse <i>Pediculus humanus</i>	Man
Endemic or murine typhus	<i>R. mooseri</i> (= <i>R. muricola</i>)	Worldwide	Rat flea <i>Xenopsylla cheopis</i>	Rat (squirrel shrew)
Tsutsugamushi disease	<i>R. orientalis</i> (= <i>R. tsutsugamushi</i>)	Japan Formosa, Malaya, Java, Sumatra, New Guinea, North Queensland	Larva of <i>Trombicula akamushi</i> (Japan) <i>T. deliensis</i> (India) <i>T. fletcheri</i> (New Guinea)	Vole Rat Bandicoot
Trench fever	<i>R. quintana</i> (= <i>R. volhynica</i> and probably <i>R. weigli</i>)	North Africa	Louse <i>P. humanus</i>	Man
Rocky Mountain spotted fever (Eastern and Western forms)	<i>Dermacentor xenus rickettsi</i>	U S A	<i>Dermacentor andersoni</i> <i>D. variabilis</i>	Goats, hares and other rodents Dogs
São Paulo rural typhus	<i>D. rickettsi</i> var <i>brasiliensis</i>	Southern Brazil	Tick <i>Amblyomma cajennense</i>	Opossum Dog
Fievre boutonneuse	<i>D. rickettsi</i> var <i>canis</i>	Mediterranean zone	Dog tick <i>Rhipicephalus sanguineus</i>	Dog
South African tick typhus	<i>D. rickettsi</i> var <i>puppers</i>	South Africa ¹	Tick <i>Hæmaphysalis leachi</i>	Dog
'Q' fever	<i>Rickettsia burnetti</i> (= <i>R. diaporica</i>)	Australia, U S A	Ticks <i>Hæmaphysalis humerosa</i> <i>Dermacentor andersoni</i> <i>D. occidentalis</i> <i>Amblyomma americanum</i> <i>Rhipicephalus sanguineus</i> ?	Bandicoot

FLEA TYPHUS

Synonyms — Murine Typhus, Hone's Disease, Ship Typhus, Typhus Muris, Endemic Typhus, Urban Tropical Typhus, Shop Typhus

¹ Tick borne typhus also occurs in Abyssinia and in Kenya where the dog tick *Rhipicephalus sanguineus* acts as vector

Definition—A mild typhus-like fever, with a worldwide distribution, occurring in non epidemic form, and caused by *Rickettsia mooseri*. It is conveyed to man by the rat flea, *Xenopsylla cheopis*, from infected rats or other rodents which are natural reservoirs of the disease.

Ætiology—That some connection might exist between the handling of grain and rats was first suggested by Hone (1922) in South Australia. Dyer and others (1931) found that fleas collected from rats and injected into guinea pigs produced the disease. Nicolle (1933) described the same disease under the title "Typhus murin" in sailors in French warships.

R. mooseri has a similar morphology to *R. prowazeki*, which causes epidemic typhus, and the Weil-Felix reaction with OX19 strains is similarly positive in the two diseases. The two diseases can be differentiated serologically only by complement fixation and agglutination tests with rickettsial antigens. They also differ inasmuch as *R. mooseri* gives a positive scrotal reaction when inoculated into guinea pigs. It may be most important to differentiate early between outbreaks of epidemic (louse-borne) and murine (flea borne) typhus.

Pathology—Patients rarely die with flea borne typhus, but there is no evidence that the lesions differ from those of mild epidemic typhus. In infected animals pathological changes are very similar to those caused by *R. prowazeki* except in the guinea pig where the scrotum becomes dusky red, swollen and inflamed, the tunica is thickened and may show hemorrhage and exudate, and the testicle is swollen. Rickettsiæ are found in large numbers in the cytoplasm of the serosal cells of the tunica vaginalis. This is known as the Neill-Mooser reaction, and is feeble and inconsistent with *R. prowazeki*.

Symptoms—The incubation period is generally 8 to 14 days. As a rule the onset is rapid, with chilliness or a mild rigor and moderate temperature or it may start more gradually with irregular initial symptoms and slowly increasing fever. The face becomes flushed, the conjunctivæ are somewhat injected, and headache pains in the back and cough, perhaps associated with pulmonary basal congestion are commonly found. The rash usually appears about the fourth or fifth day, on the chest, abdomen and inner surfaces of the arms, extending later to other parts. It consists of rose red or dusky red macules fading on pressure and, unlike classical louse typhus, petechiæ are uncommon. In dark-skinned people the rash may be so inconspicuous as to be missed altogether. The fever lasts 7 to 14 days, the temperature falling by lysis.

Complications are few, but broncho-pneumonia and pleurisy with effusion may occasionally supervene.

Diagnosis—A history of association with rats, the mild nature of the illness and the strongly positive Weil-Felix reaction to OX19 strain of *Proteus* with negative agglutination to OXK and OX2 antigens will generally enable a diagnosis to be made, especially if the disease occurs in countries where louse typhus is not endemic.

Course and Prognosis—The disease runs a mild course, has a low case mortality rate (1 per cent or under) and convalescence is rapidly established.

Treatment—PROPHYLAXIS consists essentially in rat proofing, rat destruction and the avoidance of contact with rats. Experimentally induced immunity is good against the murine strains of rickettsia, but owing to the sporadic nature and mildness of the disease large scale vaccination is unnecessary.

The general measures adopted in mite and louse typhus are also applicable. Chlorotetracycline, oxytetracycline and chloramphenicol are all remarkably effective. Response is very rapid, fever usually subsiding in 24 to 48 hours. Mortality is very low in treated cases. The antibiotics are usually administered orally. An initial loading dose of 2 to 3 g. (for a patient weighing 70 lb) is given in the course of 2 hours and is followed by 0.5 g. 6-hourly until the temperature has been normal for 2 days.

MITE TYPHUS

A number of varieties of mite typhus has been described due to the one virus, *R. orientalis* or *R. tsutsugamushi*. For many years the scrub or rural form of tropical typhus described by Fletcher in the Federated Malay States, and transmitted by *Trombicula deliensis* from infected rats, was regarded as differing from tsutsugamushi disease in as much as there was supposed to be an absence of a primary lesion, lymphangitis and bubo. Lewthwaite and Savor (1940) have now identified the two viruses, and shown that in rural typhus there may be either a persisting eschar or a fleeting papular lesion which often escapes recognition by its disappearance before the onset of other symptoms. The local lesion is common in the white-skinned European and rare in the dark-skinned Tamil. In Sumatra the pseudo-typhus of Deli, transmitted by *T. deliensis* from infected rats, is also identical with tsutsugamushi; though the mortality is only 5 per cent. in the indigenous population, it may be as high as 40 per cent. in Europeans. Similarly, scrub typhus encountered in India, Ceylon, Burma, Indo-China, the Philippines, the Dutch East Indies, New Guinea and on the mainland of Australia in North Queensland is transmitted by larval mites, and the virus is identical with that of tsutsugamushi disease. A remarkable feature noted in New Guinea, as elsewhere, is the variable virulence of the virus, the mortality rate in different localities varying from 1 to 30 per cent. This variable virulence is probably dependent on different strains of the one virus, though the size of the infecting dose may also be a factor.

TSUTSUGAMUSHI DISEASE

Synonyms.—Japanese River Fever; Mite Typhus; Scrub Typhus; Rural or Scrub Tropical Typhus; Pseudo-Typhoid of Deli; Sumatra Mite Fever.

Definition.—An acute disease of the typhus group characterised by fever of 2 to 3 weeks' duration, a primary sore or eschar associated with local adenitis, a maculo-papular rash, generalised lymphatic glandular enlargement, deafness and symptoms of basal pulmonary congestion. It is caused by *Rickettsia orientalis* and is transmitted from infected field mice (voles) or rats to man by the bite of certain larval mites of the genus *Trombicula*.

Ætiology.—In Japan the disease occurs commonly in the summer amongst harvesters handling the hemp crop in the Island of Nippon. Here the vole, *Microtus montebellii*, is the reservoir host. Trombiculid mites pass through four stages in their development, but it is only the larval stage which can transmit infection to man. The rodent reservoirs in Sumatra, Malaya and New Guinea are rats, and, as in the case of voles in Japan, the red hexapod larvæ (100–200 μ) are found inside the ears of their rodent hosts. The larval mite needs one feed on animal tissue-fluid for its metamorphosis, and is liable to get on to people walking through the jungle, lying on infected ground, or sitting on logs. Having attached itself to the skin and fed, the engorged larval mite drops off and passes through the nymph stage to become adult. The nymphs and adults feed exclusively on plant juices. The adults, which are only about 1 mm long and 0.5 mm. wide, live in soil to the depth of a few inches, and presumably deposit their eggs on the ground, where a new larval generation hatches out. Larval mites live on the ground and in rotting leaves, but they may climb up a few inches on the stems of Kunai grass, etc., or even higher on to rotten logs when stimulated by the presence of man. Once the virus is acquired by a mite larva it can pass on continuously from the adult to the egg and larva, which transmits the disease at its next animal feed. It is important to demarcate accurately any area where the disease has been acquired, so that subsequent exposure of troops or civilians

to infection may be avoided. *I. akamushi* transmits in Japan, *I. deliensis* in Malaya and India and *T. fletcheri* in New Guinea.

There is no necessary relationship between scrub itch and scrub typhus, as the species of trombiculid mite, such as *T. minor*, which produces the former may not be a vector of the latter. Some hours after being bitten by uninfected mites, hypersensitive persons develop itchy papules, which may vesiculate and later become infected with pyogenic bacteria. Large numbers of these close-set lesions may be observed round the waist, or on the legs, etc. If an infected mite inoculates rickettsiæ while biting, a primary sore or eschar is liable to result, due to multiplication of these organisms *in situ*.

Pathology.—The local eschar, with inflammatory enlargement of the regional lymph glands, petechial hæmorrhages involving the serous membranes and alimentary tract, bilateral pulmonary congestion, generalised adenitis, including the tracheo-bronchial and mesenteric lymph glands, a flabby heart, with or without dilatation of its cavities and degeneration of the kidneys and liver are typical findings at necropsy. The brain may show œdema, increase in the cerebrospinal fluid and congestion of the superficial cortical vessels. Occasionally thrombotic lesions, such as pulmonary infarction or femoral thrombosis, are encountered, but, unlike louse borne typhus, widespread thrombosis of the peripheral blood vessels is rare, and rickettsiæ in the endothelial cells lining the blood vessels are exceedingly difficult to demonstrate. Histopathological findings include perivascular cell infiltration, extravasation of red blood corpuscles due to degeneration of the endothelial cells lining the small vessels and degenerative toxic changes in the parenchymatous cells of the spleen, liver and heart muscle.

Symptoms.—A small papule may be evident some 2 or 3 days after the attachment of the larval mite to the skin. This either subsides or may develop into a typical eschar. At the onset of the fever the eschar is a small rounded or oval sore 2 to 4 mm in diameter, surrounded by a raised dusky areola 3 to 4 mm in width. There is a firmly attached necrotic centre, which later develops into a black slough, this separates from the tenth day onwards, producing a punched-out ulcer. Healing occurs in 3 to 4 weeks, leaving a pitted scar which is occasionally pigmented. Eschars are demonstrable in about 60 per cent of European cases, they are generally single but occasionally may be multiple, as many as 6 being recorded. The site of the eschar is largely determined by the type of clothing worn. With open shirt, shorts and stockings the lesion appears on the neck or the calf at the upper margin of the stocking. When trousers and gutters are worn the legs are rarely affected, the common site being the arms and axillæ (30 per cent), chest and neck (20 per cent) and the thighs and buttocks (27 per cent) (Williams, Sinclair and Jackson).

Fever commences some 5 to 14 days after the bite (incubation period). The onset is generally sudden, with a rise in temperature (99° to 102° F), malaise, head ache, post-orbital pain, shivering, rigors, aching pains in the back and limbs and perhaps vomiting. Occasionally there is a period with mild malaise and headache for 2 or 3 days prior to the onset of fever.

In the typical case a high temperature is soon established—103° to 104° F being usual and up to 105° F not uncommon. A 4-hourly chart often reveals marked irregularities, the temperature being remittent, intermittent or continuous. In some, the temperature is continuous with little tendency to remittency, in others an intermittent type of temperature is common for the first 10 to 14 days, after which the temperature tends to become continuous and subsides by lysis on the fourteenth to seventeenth day. Injected conjunctivæ, a furred cracked tongue, anorexia and constipation are frequent, and diarrhœa and abdominal distension occur in a few instances. Characteristic features appearing near the end of the first week include (1) generalised enlargement of the lymphatic glands, (2) a maculo-papular eruption, (3) pulmonary features, (4) mental symptoms and (5) transient nerve deafness.

During the second and third weeks prostration and mental symptoms increase, the early euphoria being replaced by irritability, sleeplessness, delirium or apathy and drowsiness. The cough becomes increasingly troublesome, there is considerable loss of weight, tremor may be marked and the superficial abdominal reflexes and knee and ankle jerks are decreased or absent. The heart sounds soften and, in severe cases, the blood pressure tends to fall markedly, the skin assumes a dusky hue and the tissues over the ankles and sacrum may pit on pressure, occasionally there is incontinence of faeces and urine, with increased risk of bed sores developing. The patient may die from peripheral circulatory failure or coma in the third week or the fever may subside by lysis with drenching sweats and steady improvement. Though the febrile stage of the disease does not generally exceed 3 weeks severe cases do occur where fever continues for 4 to 6 weeks, in most of these there is some complication, such as an infected pulmonary infarct. In the average case the patient is normally well in 6 weeks and fit to resume his ordinary vocation within 3 months.

In dark-skinned Asiatics the eschar is not readily demonstrable and the rash may be so inconspicuous that it passes unnoticed. Mild suffusion of the eye associated with photophobia, fever, mild cough, headache, deafness and slight enlargement of the glands may be the only noteworthy clinical features (Lewthwaite and Savoor).

In the *mild type* the onset and course of the fever are similar, but mental changes are inconspicuous, the blood pressure is well maintained, cyanosis and oedema of the feet are absent, and the pulmonary features are transient. Such patients are well at the end of 3 weeks and fit to work in 6 to 8 weeks.

In the *ambulatory type* symptoms are so mild that the patient does not feel sufficiently ill to take to bed, positive agglutination reactions are the only criterion of diagnosis in such cases.

Special features—The characteristic eschar has already been described, but certain other features call for more detailed description.

(1) *Adenitis*—By the fifth day there is often slight or moderate enlargement of the lymphatic glands, which are discrete, elastic and firm. The axillary, and superficial and deep inguinal glands are commonly affected, the cervical and epitrochlear glands less frequently. The most marked enlargement is found in the regional lymph glands draining the eschar, but even here tenderness is not marked unless secondary infection has supervened.

(2) *Rash*—Some 50 to 70 per cent of European patients develop a maculopapular rash, fading on pressure. Macules first appear on the chest and abdomen from the fifth to eighth day, soon become slightly raised, assuming a maculopapular appearance, and within 48 hours may spread to the face, neck, arms, palms of the hands, trunk, thighs, legs and soles of the feet. When fully developed these maculopapular lesions have a diameter of from 2 mm to 1 cm and a dull-red appearance, they commence to fade within 4 to 5 days and have usually disappeared by the fourteenth day of the disease. Macules may occasionally be observed on the soft palate. Sometimes the papular element may be lacking, and the small closely packed macules then simulate the rash of dengue or measles. In fatal cases the rash occasionally becomes petechial (Williams, Sinclair and Jackson).

Pulmonary features—Cough is common early in the disease, and rales and rhonchi are frequently noted. Chest pain is not uncommon. Signs in the lungs appear from the seventh day onwards, but in milder infections these features are transient and do not progress as in the seriously ill, in whom dullness, diminished vesicular murmur, abundant crepitations, rales and rhonchi are audible over both lower lobes. These features are accompanied by the development of cyanosis of the lips and an increased respiratory rate to 40 or thereabouts. Mouth breathing is frequent, and there is an irritating cough, with tenacious white or blood-streaked frothy, non-

purulent sputum In cases which recover, these abnormal chest signs begin to disappear at the end of the third week

Nervous system—Mental features are common in the seriously ill patient During the first 4 days the mental state is generally normal, any change noted being towards euphoria or apathy From the sixth to tenth day ill patients show more pronounced changes In some the initial euphoria increases, and restless irritability, toxic confusion, insomnia and delirium supervene Others become atonic, apathetic, drowsy and stuporous Coma not infrequently precedes death With clinical recovery, the mental state returns to normal

Neurological features include nerve deafness, tremor, photophobia, tinnitus, paræsthesia, hyperæsthesia, neuritic pains, depressed superficial and deep reflexes, and urinary incontinence and retention Nerve deafness, which is a characteristic feature, is generally bilateral It appears about the fifth day and rarely lasts longer than a week, permanent deafness being very rare Headache and neck stiffness may be associated with increased cerebrospinal fluid pressure

The cerebrospinal fluid is often normal, but may show increased lymphocytes, increased protein and decreased chlorides These changes are most commonly found about the tenth day, disappear with recovery and are not necessarily related to neurological complications

Cardiovascular features—The pulse-rate is slower than would be anticipated from the temperature during the first week, it quickens to between 90 to 120 per minute during the second week In non fatal cases the pulse is regular in rhythm but may be dicrotic during the second and third week With cessation of fever the heart rate soon returns to normal, and during convalescence significant cardiac abnormalities are rare From the second week onwards in severe cases the blood pressure tends to fall, the daily readings being 75-100 mm Hg systolic and 35-60 mm Hg diastolic Fatal cases not infrequently die with peripheral cardiovascular failure After recovery it takes about 2 weeks for the blood pressure to become normal

Laboratory findings—The serum gives a positive agglutination to *Proteus* OXK suspensions, not to OX19 or OX2 The agglutinin commences to increase about the seventh day, reaching a maximum titre about the twentieth day For this reason it is sound practice to examine the blood at weekly intervals, commencing during the first week and keeping some of the first serum for subsequent tests In cases in which only one test is done, an arbitrary minimum diagnostic titre of 1/125 can be provisionally accepted as diagnostic of an active infection, but as Felix points out, suspensions of *Proteus* OXK are more susceptible to non specific "normal" agglutination by sera from man than are suspensions of OX19 and OX2, and for this reason additional caution is necessary in making a diagnosis on the basis of a low titre agglutination reaction

The leucocyte count varies within fairly large limits and neutropenia is not uncommon During the first 9 days the count tends to be of low normal type, i.e. 4000 to 7000 cells per c mm, later it increases The lymphocytes are on an average below 2000 per c mm, but increase later in cases which recover, in fatal cases the count frequently remains below 2000 per c mm (Williams, Sinclair and Jackson)

Anæmia is not a marked feature Hæmoglobin may be decreased by 2 to 3 g per 100 ml, with an equivalent reduction in erythrocytes Mild albuminuria is the rule, and in severe cases this increases and hyalo granular casts appear

Complications—These include parotitis broncho pneumonia, pleurisy with effusion and infarction Infarcts may become secondarily infected and lead to lung abscess Femoral thrombosis may develop in the second or third week, and suppuration may occur in the course of the vein Eye complications include conjunctival hæmorrhage, retinal hæmorrhage and rarely thrombosis of the retinal artery with

Ætiology.—The disease primarily affects wild rodents, and, as shown by Wilson and Chowning (1904), is conveyed to man by ticks. Larval and nymph ticks transmit the virus from rodent to rodent, but human beings are usually infected by adult ticks of the species *D. andersoni*, *D. variabilis*, *A. americanum* and *A. cajennense*. Infected ticks transmit the infection to their offspring and serve not only as a vector but as a reservoir for rickettsiæ. The causal organism, *D. rickettsi*, was described by Ricketts (1909) in the blood of guinea-pigs and monkeys infected with Rocky Mountain spotted fever. *D. rickettsi* produces a well-marked scrotal reaction in inoculated guinea-pigs, and can be demonstrated in the fluid exudate of the tunica vaginalis prior to generalised dissemination in the blood stream.

Most infections are found in people whose occupations brings them in contact with ticks. Where town dwellers are affected, dogs probably are implicated. Most cases occur in April and May in the Rocky Mountains, and in the summer in the Eastern States of the U.S.A.

Pathology.—Pathological changes include petechial hæmorrhages involving the skin and serous membrane, enlargement of the spleen and lymph glands, and degenerative changes in the kidneys, liver and heart. The essential lesion is an acute infection of the small blood vessels throughout the body, particularly in the skin and brain. Proliferation of the vascular endothelium often leads to thrombosis and possible secondary gangrene. *D. rickettsi* is found within the nuclei of mesothelial cells, not in the cytoplasm as with *R. prowazeki*.

Symptoms.—The incubation period is from 3 to 14 days. A local lesion at the site of the tick bite with adenitis is rare. The onset is generally sudden, with headache, lumbar and generalised pains, and sometimes sweating, rigors, anorexia, malaise and vomiting. The tongue is coated, the conjunctivæ injected and the temperature rises rapidly to 103° or 104° F, the maximum being reached in 3 or 4 days' time. By then, in severe cases, the face is becoming dusky and a rose-red macular or papular rash appears. Later the macules turn darker, cease to fade on pressure and may become obviously hæmorrhagic. The rash is first seen on the wrists and ankles, later it extends to the body generally, including the palms, soles and face. The fever lasts 2 or 3 weeks, and falls by rapid lysis. Constipation, restlessness and insomnia are usual, while severe cases may show stupor, delirium, coma and convulsions. Enlargement of the spleen is not uncommon, and may be an early feature. Later there may be jaundice and hepatomegaly and, where the central nervous system is involved, altered reflexes, and Babinski's and Kernig's signs may be elicited. A leucocytosis of 15,000 to 20,000 per cmm is not infrequent, but leucopenia may occur, the lymphocytes are increased. Albuminuria is the rule in severe cases.

Apart from this average classical type there are abortive cases, with transient fever lasting 3 or 4 days, ambulatory cases, with scanty rash and fever lasting 7 to 10 days, and fulminating cases, which die with marked nervous symptoms either before the rash has appeared or with a hæmorrhagic type of eruption.

Complications and Sequelæ.—Convalescence tends to be prolonged, especially in severe cases. Bronchitis, pneumonia, femoral and other thromboses, parotitis, hæmaturia, epistaxis and melæna may complicate the picture. Iritis, nephritis, otitis media and gangrene of the fingers, toes, tonsils, prepuce and scrotum have been recorded.

Diagnosis.—The differential diagnosis includes epidemic and other forms of typhus, typhoid and the paratyphoid fevers, and cerebrospinal meningitis. Geographical considerations, the character of the rash and the serological and other laboratory findings are of importance. Positive serological reaction may be obtained with OX19 strains of *Proteus*, but more specific results have recently been obtained by means of complement fixation tests employing purified rickettsial suspensions as antigen.

Prognosis—The mortality rate varies from 5 to 90 per cent in different geographical areas. Apart from fulminating cases, the onset of profound nervous symptoms, severe cardio vascular depression and a hæmorrhagic rash indicate a severe infection and imply a correspondingly grave prognosis. Age is of great importance, the higher age groups having a high mortality.

Treatment—In endemic areas tick-proof clothing should be worn and the body carefully searched for ticks, iodine should be applied locally after their removal. A prophylactic vaccine prepared from a killed suspension of specific rickettsiæ should be given in endemic areas and repeated each year. Specific treatment with chlor-tetracycline, oxytetracycline or chloramphenicol (Chloromycetin) is similar to that described on p. 287.

N HAMILTON FAIRLEY.

LOUSE-BORNE TYPHUS FEVER

Synonyms—Typhus Exanthematicus, Epidemic Typhus, Fleck Typhus, Jail or Camp Fever.

Definition—An acute louse-borne infection due to *Rickettsia prowazeki* and characterised by continued fever, a maculo papular eruption, nervous irritability and profound prostration. In favourable cases rapid defervescence occurs about the fourteenth day.

Ætiology—The infection is conveyed by body lice perhaps through their bites, but more probably by cutaneous inoculation of their excreta by scratching. Head lice are also possible vectors. The disease is one of a group transmitted by lice, rat fleas, ticks and larval mites but differs from the others in that it has a human and not an animal reservoir. Typhus fever can also be transmitted sporadically by the rat flea, but in epidemics the body louse is the infecting agent. Most of the factors which conduce to the spread of typhus operate by their influence on the parasites by which the disease is conveyed. The lice pass directly from the sick to the healthy, or indirectly by means of garments, in the seams and folds of which they naturally live or by bedclothes and mattresses. They migrate from the dead. Lice which have fed on infected persons can, after a few days, transmit the disease and remain infective for the rest of their short lives. Their eggs also contain the infective agent. Their dried faeces remain infective for many months and may possibly be air-borne as dust and inhaled. The conjunctivæ are also possible portals of entry. Infected lice die in about 11 days, but the rat flea remains alive and infectious for several months. Crowding of the sick together in dark, ill ventilated rooms greatly favours the possibility of infection, whilst in the presence of free ventilation very close contact is necessary before the disease is contracted.

Typhus carriers are always verminous persons. Clothes which harbour infected lice have also transmitted the disease to distant parts. Typhus is a disease of cold and temperate climates, it occurs in those months when confinement within doors and overcrowding are most likely, but paradoxically the peak of prevalence in countries where it is endemic may occur in March, April and May. In hot climates bathing, scantiness of attire, free action of the skin and the lethal effect of high temperatures on lice are all factors which prevent its spread. But even here it may be found at high altitudes. Predisposing causes of epidemics are verminous infestation, overcrowding, mass movements of the population and, above all, starvation. Epidemics are particularly liable to occur in times of war and famine.

In Russia, Eastern Europe and Asia Minor the disease is very prevalent. An endemic form of typhus fever, due to *R. mooseri*, is of wide distribution. It is transmitted by the rat flea, *Xenopsylla cheopis*, and the rat is the reservoir of infection. This endemic or murine form has been observed in Africa, Greece, China, and North

and South America. The murine strain occasionally gives rise to epidemics, as, for instance, in Mexican typhus or tabardillo when the agent is louse-borne. Brill's disease, on the other hand, is an endemic form of typhus due to *R. protoazeki* believed to have been imported into the towns of the North American Atlantic seaboard by immigrants from Central Europe.

Typhus attacks persons of all ages and both sexes. The greatest mortality is in those above middle age, at 50 years it may be 50 per cent., and between 75 and 80 years nearly 85 per cent.; attacks in the young are less severe and very much less fatal. The average mortality is 10 to 20 per cent. In populations where the disease is endemic attacks may be very mild, but when introduced into other places the same strain may prove excessively severe. In Brill's disease the mortality is less than 1 per cent. By some this low mortality is attributed to a previously acquired immunity or even to recrudescence of a latent infection. As a rule not only does louse-borne typhus protect against itself but also, it is stated, affords protection against the endemic flea-borne variety.

Pathology.—The naked-eye post-mortem appearances are those common to many acute infections and are not in themselves distinctive. Petechial hæmorrhages in the skin, serous and mucous membranes and bronchiolitis or a general catarrh of the air passages and hypostatic congestion of the lungs are common. Softening of the spleen and inflammatory lesions of the kidneys, heart and testes may occur. The absence of ulcerative lesions in the bowel affords a distinction from typhoid fever. Beyond occasional meningeal congestion the central nervous system appears normal. Zenker's degeneration of muscle may be found.

Microscopical examination reveals discrete nodules of endothelial proliferation widespread in small arteries of the conjunctivæ, the skin, the brain-stem and elsewhere. These foci are surrounded by a characteristic perivascular infiltration of large mononuclear and plasma cells. The lesions may initiate thromboses or by necrosis give rise to small hæmorrhages. They are known as typhus nodules.

Prime importance is attached to Rickettsia bodies (*R. protoazeki*). These are small and pleomorphic, not more than 0.3 by 0.4μ in size. They lie in the cytoplasm of cells, are Gram-negative and stain by Giemsa's stain. Rickettsia bodies are found sparingly in the blood on the seventh to the twelfth day of the disease, and also in infected lice and their excreta. Similar bodies occur in the typhus nodules and in the endothelial cells of the liver.

An agglutinative phenomenon, the Weil-Felix reaction, affords a valuable means of recognising typhus. The reaction is named after two observers who discovered in the urine of patients suffering from typhus an organism of the *Proteus* group which is agglutinated in high dilution by the serum of those infected. Two strains of the bacillus are concerned OX19 and OX2, and agglutinations have been obtained with dilutions of serum up to 1 in 30,000. Reactions in controls, if occurring at all, do not take place in dilutions exceeding 1 in 50 or, at most, 1 in 100. In half the cases of typhus the reaction is found by the fifth day, and in practically all by the tenth day, after which the titre rises for about a week. There is, however, no proof that either *Proteus* OX19 or OX2 is capable of producing typhus, nor does it confer immunity to the disease. An agglutination test with Rickettsia bodies has also been elaborated (Weigl reaction).

The Wassermann reaction is often positive in typhus if the blood is examined before the crisis, but becomes negative again in convalescence. In inoculated persons the titre of the Widal reaction for typhoid rises steadily. This is an anamnestic reaction.

Symptoms.—The incubation period is about 12 days with extremes of 5 to 21.

The classical onset is sudden and ingravescence much more rapid than in typhoid. Distressing headache, giddiness, shivering or rigor and often vomiting mark the accession. Pains in the limbs and back may be severe and muscular prostration

evident from the first. Drenching sweats may occur. The face is flushed or dusky, the conjunctivæ injected, sometimes chemotic, and the pupils contracted. A characteristic nervous irritability leads to restlessness, photophobia and insomnia. The tongue is large and coated, but soon becomes dry. Appetite is lost, thirst is great and the bowels are generally constipated. The urine is high coloured and scanty, rich in urea and uric acid, but deficient in chlorides. Albumin may appear later and the diazo-reaction is very constant. Bronchitis and slight epistaxis may occur. The spleen may become palpable, but the abdomen is not tumid. Even thus early in the disease, especially in alcoholic subjects, marked delirium, mania or stupor may be present. The patient soon takes to his bed. The temperature may reach 104° F. by the first night; the acme, however, is generally attained on the third or fourth day. Associated with the fever is a somewhat rapid soft pulse. Marked rapidity of the respirations is also noticeable and may lead to an erroneous diagnosis of pneumonia.

The fever, which during the invasive stage may show remissions, after attaining its maximum, which may be as high as 105° or 106° F., undergoes little or no daily variation. At the end of the first week or a day or two later a sudden remission, which is rarely lasting, may occur (*pseudo-crisis*); from this period, however, the fever generally shows some abatement and a sudden or somewhat gradual defervescence sets in on the thirteenth to the seventeenth day of the disease.

The rash appears on the fourth or fifth day, first on the axillary folds, about the shoulders and on the sides of the chest and the abdomen. It avoids the face, and rarely invades the temples and forehead, nor does it appear on the palate, and seldom on the palms and soles, with these exceptions it may become general all over the body. It is most profuse on the trunk, especially on the back. The elements of which it consists are macules, papules and petechiæ. The macular elements of the rash generally appear before the papules. They are large, blotchy and dusky in tint. With them is associated a deep-seated erythema or "subcuticular mottling". This mottling is best seen about the shoulders and axillæ, but often extends to the back and front of the chest, the thighs and arms. The papules resemble the rose spots of typhoid, but are often ill-defined. At first they fade on pressure; later, unlike the spots in typhoid, they may show petechiæ, becoming dull red or brown and indelible. They do not appear in successive crops.

Petechiæ which resemble flea-bites may appear on the skin and in the conjunctivæ of the lower lids. Purpuric patches may form over pressure-points and terminate in gangrenous bed-sores. The purpura indicates a severe infection, the hæmorrhagic character of which may be confirmed by the occurrence of hæmatemesis, melæna or hæmaturia. Profusion of the rash in typhus is also an indication of a severe attack. In mild cases the eruption is scanty, and in children it is very evanescent. The application of a tourniquet will cause petechial hæmorrhages within the rash.

The polymorphonuclear cells of the blood, which may possibly at first be increased, include many immature forms. A lymphopenia in the early stages is later replaced by a lymphocytosis, and basophilic mononuclear cells, Turk cells and plasma cells become numerous.

The cerebrospinal fluid may show a slight lymphocytosis, and also give a low positive Weil-Felix reaction. The globulin is increased.

During the second week the patient in a grave infection may enter on the terminal stage of his disease. There is less complaint of headache; delirium, if present, is less violent and of a muttering rather than maniacal type. Delusions may occur. Prostration is extreme and sleeplessness pronounced. The face is dusky, sordes accumulate on the teeth. A curious mousy odour emanates from the body and dehydration becomes marked. Day by day the nervous depression increases and the patient lies helpless on his back with a tendency to sink down in the bed. The pupils are pin-point, the eyes half open and fixed (*coma vigil*). Although deaf and unnoticing,

he mutters hoarsely and incoherently and can be roused with some difficulty. The tongue is brown and tremulous or lies shrivelled in the floor of the mouth, it cannot be protruded. Tremors of tendons increase, and picking at the bedclothes is apt to occur. The pulse quickens and may reach 130 or 140 per minute. It is dicrotic or almost imperceptible. The heart's impulse is feeble and the first sound faint or inaudible. The blood pressure falls steadily. Acceleration of respiration is more than ever pronounced, 40 per minute not being unusual, the breathing becomes shallow, and hypostatic congestion of the lung bases sets in. The urine may be retained or passed into the bed. The blood urea rises rapidly, oliguria or anuria may occur and uræmia supervene. Bed sores are apt to form. The patient may pass away in coma, or hyperpyrexia may precede death.

In favourable cases the symptoms are of less severity and on the fourteenth day sometimes earlier, sometimes later, defervescence occurs. The condition rapidly improves, the temperature falls, sometimes abruptly, perhaps more frequently the fall is a little more gradual. Sleep ensues and the patient awakes from his stupor with a moist tongue and skin, a clearer intellect, polyuria and perhaps a slight critical diarrhoea. Inclination for food returns, but there is still extreme weakness. Some failing to rally after the crisis fall into a state of collapse.

In less severe cases where the typhoid state has not been pronounced, the defervescence may occur rather earlier and recovery be much more rapid, this is especially the case with children but, as a rule, convalescence is prolonged.

VARIETIES—Typhus infection may occur in all degrees of intensity from extreme mildness to fulminant severity. The milder types are particularly seen among the natives of localities where the disease is endemic, and in children. They may appear in the guise of an influenza like fever with headache, drowsiness and suffusion of the eyes, or as a broncho-pneumonia. Of the severe types that known as *typhus siderans* or *blasting typhus* is the most striking. In this form death may occur within 2 or 3 days of the onset. A meningeal variety, accompanied by head retraction, ptosis, squint and other nervous symptoms, simulates meningitis, which may indeed be present. Some cases are characterised by fierce maniacal delirium. Typhus also may assume a frankly hæmorrhagic form, but this is uncommon. Relapse is almost unknown, and authentic second attacks are rare.

Complications and Sequelæ—Bronchiolitis, broncho pneumonia or hypostatic congestion of the lungs are the outstanding complications. Rarely laryngitis occurs and may lead to necrosis of the cartilages and œdema of the glottis. True lobar pneumonia is hardly ever seen. Diarrhoea is rarely troublesome, it may be accompanied by abdominal distension and even the passage of blood. Femoral thrombosis, similar to that of typhoid fever, is common. Septic or gangrenous infarcts may be formed in the lungs, and gangrene of the fingers, ears, nose or pudenda may occur. Suppurative parotitis is a marked feature of the disease, and the inflamed gland may become necrotic. Gangrenous bed sores, too, may form with great rapidity and pyæmic complications ensue. When typhus is followed by hemiplegia or other form of paralysis a vascular lesion should be suspected. Mania, melancholia and dementia are occasional sequelæ but generally clear up, although they may take several months to do so. Other complications are diffuse glomerular nephritis, cystitis, orchitis and jaundice. Pregnant women frequently abort.

Diagnosis.—For the Weil-Felix reaction a reliable smooth strain of *Proteus* OX19, is requisite. A rising agglutination titre to this organism is most significant. Results with a titre of less than 1:200 should not be accepted as positive unless the titre has risen greatly since the onset. The agglutination may become negative in the third or fourth week of convalescence. Occasionally titres with proteus OX2 exceed those of OX19.

An ethereal extract of Cox's vaccine provides an antigen for complement deviation and agglutination tests (Craigie).

As compared with *typhoid*, the onset in typhus is more sudden, prostration and nervous symptoms occur earlier and are more pronounced. The aspect is drunken, the face congested, the pupils contracted and the eyes suffused. Diarrhoea and abdominal symptoms are unusual. The eruption is more profuse and more widely distributed, and the rose spots, which are paler than those of typhoid, may show petechiae. The termination of the fever is more abrupt. Blood cultures and agglutination tests, also the steady rise in the blood urea in typhus are of great value in distinguishing the two diseases.

Lobar pneumonia, especially the apical form with meningeal symptoms, may be mistaken for typhus, but should be eliminated by repeated examination of the lungs and the presence of a marked polynuclear leucocytosis. The hypostatic pneumonia of typhus is bilateral and does not show frank signs of consolidation. Febrile herpes may occur in both diseases.

Cerebrospinal meningitis is distinguished by lumbar puncture and examination of the cerebrospinal fluid. *Encephalitis lethargica*, with fever, headache and delirium, must be distinguished by the absence of the characteristic rash of typhus, the negative Weil Felix reaction and the supervention of such signs as slight muscular rigidity, ptosis, ophthalmoplegia and a characteristic lethargy from which the patient can be roused. The cerebrospinal fluid may show a lymphocytosis, without globulin increase.

The *prodromal rashes of small pox* have been mistaken for typhus. They are distinguished by their characters and distribution and later by appearance of the focal eruption. *Uraemia* may complicate typhus but is sometimes mistaken for it. It is then distinguished by the absence of fever and rash and the condition of the urine. Difficulty occasionally arises with a fading *measles* rash, but unlike the rash of typhus this invades the face and a history of catarrhal symptoms may be obtained. The *spotted fever of the Rocky Mountains*, which is a tick typhus, closely resembles louse typhus.

In hot climates and on campaigns other possible sources of error in diagnosis are louse borne relapsing fever, epidemics of which often coincide with those of typhus and fly fever and malaria. Influenza may also lead to difficulty.

Prognosis—The mortality, which is low in childhood and adolescence, then progressively increases (see p 296). In aged patients recovery is the exception. Clinical indications of gravity are persistent sleeplessness, marked subsultus, violent delirium or convulsions, evidence of a hæmorrhagic tendency, a profuse petechial rash and continued high fever or hyperpyrexia. Failing circulation is shown by rising pulse-rate, lividity, coldness of the extremities and hypostatic congestion of the lungs. Suppression of urine and uræmic symptoms are also of grave import. A blood urea of 90 mg per 100 ml is unfavourable and it may rise to 200 mg in fatal cases. Gangrenous bed sores, extensive parotid suppuration, pyæmic symptoms and peripheral gangrene are of bad augury, as also is persistence of a leucocytosis of over 20,000. The disease is particularly deadly to alcoholics and fat subjects.

Treatment—**PROPHYLACTIC**.—Every effort must be made to get rid of lice. The patient should be stripped, the hair clipped short and the body shaved and thoroughly washed before admission to a ward. As the eggs of lice contain the virus and hatch in about 8 days, a second disinfection at the end of 10 days may be desirable. The garments of attendants should be louse proof, and attendants should also be immune or at all events below the age of 30 years. The clothing of those infected, and of contacts should not be shaken; it should be sterilised and their living rooms and their contents disinfected. The use of D D T (dichlor diphenyl trichlorethane) has proved effective when diluted and dusted between clothes and skin and also when used for impregnating the undergarments of those exposed to infection. Cases of typhus are best treated in isolation hospitals, and when the disease is epidemic good results are obtained by forbidding movements of the populace so that susceptibles are not introduced into infected areas and infection not carried to areas

hitherto free from it. Injection of the blood serum of convalescents is said to be prophylactic, but has communicated the disease.

By cultivating the virus in lice and emulsifying their mid-guts in carbolic solution Weigl produced a protective vaccine. This contains dead rickettsiae. Vaccines have since been prepared from infected mouse lung (Durand and Giroud), and from infected yolk sacs (Cox). An alum precipitated vaccine has been introduced by Osborn. Vaccines which consist of dead organisms do not appear to afford complete protection, but those containing living organisms have at times proved dangerous.

Quarantine or supervision of immediate contacts for at least 15 days is usually recommended.

CURATIVE—This should be on the same lines as those adopted in typhoid fever. Free ventilation, tepid sponging night and morning, careful attention to the mouth and back, and the adoption of a fluid diet, consisting of milk, beef tea, fruit juice and plenty of water, are the essentials. The bowels are usually constipated and enemas should be used. The urine must be measured, suppression is dangerous and enemas may lead to great restlessness with constant overflow. When the temperature is above 103° or 104° F, tepid or cold sponging should be repeated. In hot climates exposure to heat has a very deleterious effect. For sleeplessness, paraldehyde is most useful hypnotic, but requires to be given in large doses. Wildly delirious patients need some form of restraint and in these cases hyoscine should be injected if other means fail. Frequent rectal salines or the administration of glucose solution intravenously, subcutaneously or by drip through Ryle's stomach tube are beneficial in toxæmia, dehydration and circulatory collapse. The tendency to collapse after the crisis should be remembered, and patients carefully watched at this period.

Both chlortetracycline and chloramphenicol have proved effective in the treatment of typhus fever. Improvement begins within 24 hours of administration, the temperature falls to normal usually by the third day and the rash begins to fade. This improvement is noted irrespective of the stage of the illness at which the drug is given. In view of the dangerous effects of chloramphenicol on the bone marrow in some patients, chlortetracycline must be regarded as the drug of choice.

R. BODLEY SCOTT

TRENCH FEVER

Synonyms—Volhynia Fever, Meuse Fever, Five Day or Quintan Fever.

Definition—Trench fever is a specific infectious disease, probably caused by *Rickettsia quintana*, transmitted from man to man by the body louse, *Pediculus corporis*. Clinically it is characterised by recurrent pyrexia, headache, giddiness, severe pain in the back and limbs, conjunctival congestion, sweating, leucocytosis and splenomegaly.

Etiology—The disease was first recognised as a specific entity during the War of 1914–1918, when it appeared on the European fighting fronts, Salonika, Egypt and Mesopotamia. Approximately 800,000 cases occurred amongst Allied troops in France during 4 years. No outbreak of this disease was reported during the War of 1939–1945. The inoculation of blood of infected patients into volunteers was found to be capable of causing the disease (McNee, Renshaw and Brunt). It was also proved that the blood may remain infective for 200 days. Later, it was discovered that lice which had been fed on febrile patients and were subsequently kept for 5 to 12 days at 26° to 30° C could transmit the disease to volunteers. Once infected the lice remain infected for life. Large numbers of rickettsial bodies (*R. quintana*) were demonstrated in the mid gut of lice fed on infected people (Topfer). The disease is probably conveyed not by the bite of the infected louse but by its excreta being rubbed into skin abrasions.

Pathology—As the disease never proved fatal no record of necropsies are available.

able in man. Examination of the trench fever macules in skin obtained at biopsy has shown (1) hyperæmia, (2) œdema and (3) perivascular lymphocytic infiltration, unlike epidemic typhus, there was neither necrosis of the endothelial cells lining the vessels nor hyaline thrombosis.

Symptoms—The incubation period varies from 10 to 30 days. The onset is generally sudden, with headache, giddiness, pain in the shins, back and behind the eyeballs, and a rapidly rising temperature (103° to 104° F). Chills and sweating are common. The conjunctivæ may be congested and the general appearance of the patient during the acute stage reflects extreme pain and discomfort. He is restless and changes his position constantly in a vain effort to get relief. Frontal or retro orbital headache is often severe and persistent, if it be retro occipital in type it may be accompanied by stiffness of the neck. The pain in the limbs may be of a dull aching or gnawing character, or of an acute stabbing type. Such pains are felt in the bones, especially the tibiæ, last many hours and are worse at night. At first the pain is generalised, but after a few days it becomes more localised in the loins and lower limbs. It is generally symmetrical, and may vary in situation from day to day. Associated with pain there may be intense superficial tenderness—especially over the shins—so that even the weight of the bedclothes cannot be borne.

Splenic enlargement occurs in 70 to 80 per cent of cases. Splenomegaly may be associated with tenderness and sometimes with rigidity of the muscles in the left hypochondrium. If palpable, the edge is firm. In the early stages the spleen increases in size during febrile relapses and decreases during the afebrile periods, later, its dimensions remain more constant. Though profuse sweating is uncommon, a peculiar feature is the rapid alternations of shivering and sweating, several such attacks may occur within 24 hours. Vomiting and diarrhœa have been described but are rare, constipation is the rule. Red macules, fading on pressure and lasting from 6 to 48 hours, are frequently seen in the first few days of fever and at times during relapses. They appear in crops on the chest, abdomen and back, are at first a rose red and later a dull red colour and measure 4 to 8 mm in diameter. Herpes labialis is not infrequent.

Unlike typhus, the mental condition remains normal. The tendon reflexes are often exaggerated, and during fever lateral nystagmus may be induced by moving the eyes. A moderate neutrophil leucocytosis precedes and accompanies the fever. The total count rarely exceeds 20,000 leucocytes per c.mm., and there is a marked left shift. *Urinary symptoms include frequency and polyuria in the post febrile stage, the urine may contain a trace of albumin.*

Widely different types of temperature chart are encountered. The total duration of fever varies from a few days to several weeks, and in most instances irregularities in the temperature chart are common. When the disease was first encountered in France short types predominated, later the disease became more severe and more prolonged pyrexia was more common. Various types include (1) A short bout of fever lasting about 3 days. (2) A similar short febrile attack followed by a period of apyrexia and a febrile relapse on the sixth, seventh and eighth day. Irregular fever sometimes followed. (3) The primary fever running more or less into the relapse and producing a saddle-back type of chart. Again irregular fever might follow. (4) A definitely intermittent type of fever manifesting regular periodicity and sometimes lasting many weeks.

Complications—In patients with prolonged pyrexia, pain and sleeplessness lead in certain instances to mental depression, neurasthenia and so called disordered action of the heart (D.A.H.). The latter condition which is really a cardiac neurosis, was erroneously attributed to organic disease of the heart during the War of 1914-1918.

Diagnosis—During the early febrile stage trench fever may be mistaken for influenza, dengue, typhoid, paratyphoid, typhus, malaria, relapsing fever, undulant fever, rat bite fever and leptospirosis. Laboratory investigations will help to exclude

many of the above mentioned diseases A 5 to 6-day periodicity in the temperature should suggest the diagnosis

Prognosis—As indicated under Symptoms, the course of the disease is very variable The mortality is practically nil

Treatment—Prevention consists in delousing the individual, thoroughly disinfecting the clothing and the use of DDT No specific drugs were available, and treatment was mainly symptomatic in the War of 1914-1918 No opportunity has been afforded for testing the action of chloramphenicol

N HAMILTON FAIRLEY

"Q" FEVER

Definition—An acute febrile illness caused by *Rickettsia burneti*, characterised by sudden onset, general symptoms including headache, and usually the development of interstitial pneumonitis There is no rash and agglutinins to *Proteus* organisms do not develop

Ætiology—The causative organism, *R burneti*, is small and pleomorphic It is present in the blood during the febrile period It may also be recovered from sputum urine or CSF or from tissues especially spleen, obtained at necropsy

"Q" fever is believed to be an enzootic of animals transmitted naturally by certain ticks It is commonly transmitted to domestic stock, including cattle Ticks infesting livestock easily become infected with *R burneti* which appears in their faeces The causal organism is resistant to desiccation and is conveyed to man most commonly by inhalation of infected dust Infection may also occur through handling infected tissues secretions, etc The disease is thus found mainly in persons concerned in handling of livestock or in those exposed to dirty, dusty conditions associated with livestock Infection may result from drinking raw milk It occurs easily in laboratory workers handling *R burneti*

"Q" fever, with pulmonary involvement, can be reproduced in man by inhalation or intranasal instillation of infective material containing *R burneti* Intradermal or intramuscular inoculation of the organism may give rise to fever and rickettsæmia but without pulmonary signs

"Q" fever appears sporadically or in explosive outbreaks It was first described in 1935 in Australia It is now known to occur in many parts of the world, including England Spain, Italy, Greece, the Middle East, tropical and South Africa and the United States of America During the War of 1939-1945 localised "epidemics" occurred amongst troops stationed in the Mediterranean littoral

Pathology—*R burneti* can readily infect many wild and domesticated animals and several species of ticks, transovarial transmission has been described in the latter

Isolation of the organisms in a suspected case of "Q" fever is usually carried out by intraperitoneal inoculation of blood or urine into guinea pigs Pathological changes in infected animals include moderate enlargement and engorgement of the spleen and small granulomatous lesions in many organs

In man, *post mortem* findings have been described in very few cases The principal lesions are found in the lungs, especially in the basal zones, in which there are patchy consolidation and thickening of the alveolar walls and perivascular tissues due to accumulations of macrophages and round cells Polymorphs and red cells occur in minimal numbers There may be small scattered areas of necrosis and breaking down of alveolar septa Alveoli, bronchioles and small bronchi are filled with exudate containing large numbers of degenerate macrophages Foci of round cell and macrophage accumulations have been reported in the testes, kidneys and other organs, and similar lesions involving the microglia in the brain Intracellular and extracellular rickettsæ have been identified by Whittick in smears of lung spleen, testis and brain

Symptoms and Signs.—The incubation period is given by Smadel as a mean of 19 days. The onset is usually sudden. There is a wide variation in severity. The clinical picture may show nothing beyond a mild fever lasting only a day or two. In most cases, however, the temperature rises rapidly at first to moderate heights, but may reach 103° to 105° F. after 1 or 2 days. The fever is remittent and swinging. It lasts from 1 to 10 days or longer, the average duration being from a few days to 3 weeks. In some cases, especially in middle aged individuals, the fever persists for several weeks. General symptoms may develop at the onset and persist through the febrile period. Headache and general muscular pains are often severe. Subjective feelings of cold and occasional shivering may occur, but rigor is unusual. Nocturnal sweating and insomnia are common in some outbreaks. Anorexia and nausea are the rule. The upper respiratory tract is not usually involved, but a slight dry cough may develop after the fourth day, often accompanied by pain in the chest, which may be localised to one area. The sputum is usually mucoid or mucopurulent and may be blood-streaked, occasional small haemoptyses have been reported. In some patients dyspnoea may be the dominant picture, and there may be cyanosis. Examination of the chest at this stage may reveal localised reduction in air entry, commonly in one or both bases, with occasional crepitations and scattered rales. In seriously ill patients there may be obvious signs of consolidation in one or both bases. The physical signs of lung involvement, however, may vary considerably from day to day and are often evanescent, but evidence of pulmonary changes can usually be demonstrated by radiography. Radiographic changes are said to occur in practically all naturally infected patients. The pattern is indistinguishable from that of primary atypical pneumonia. It develops about the fourth day, when signs of consolidation appear, involving small areas of one or more lobes. The shadows present a homogeneous "ground glass" appearance. The lesions may progress for a few days and then become stationary, disappearing only slowly. They frequently persist well into convalescence.

Evidence of changes in organs other than the lungs and the spleen is uncommon. In those cases in which the febrile episode continues for weeks, however, signs of liver involvement, including jaundice, may develop.

Relapses occur weeks or months after the initial attack in a small percentage of cases, with recurrence of fever and pulmonary signs and symptoms.

Course—Complications rarely develop. Delirium and signs of acute meningo-encephalitis have been reported. Orchitis has also been described during a severe attack. Some loss of weight occurs during the febrile period and there is considerable weakness, which may persist for weeks after treatment. The appetite improves rapidly and the temperature returns to normal.

Fatal issue is rare. Deaths have been reported in a few natural infections and in a laboratory worker.

Diagnosis—Clinical diagnosis is difficult. A knowledge of the patient's employment, especially in regard to contact with livestock is essential. The early stages of "Q" fever closely resemble those of many other acute febrile illnesses, and in the stage of pulmonary involvement the diagnosis of pneumonia or atypical pneumonia is commonly made. Failure of the pulmonary condition to respond to sulphonamides or penicillin is often the first clue to the real condition. In some areas psittacosis and coccidioidomycosis must be differentiated. Diagnosis depends finally on the recovery of the organism or the results of serological examinations.

R. burneti can be recovered during the febrile stage of the illness by intraperitoneal inoculation of blood or urine into guinea-pigs. The organism is eventually identified in spleen smears from the infected animals. Because of the considerable danger of accidental infection, isolation of the organism should not be attempted except under the proper laboratory conditions.

Diagnosis is usually made by examination of the serum for agglutinins and

complement-fixing bodies. Agglutinins appear by the end of the second week and can be identified in most cases by the end of the fourth week. Complement-fixing bodies may be present by the seventh day and are at a high titre by the end of the third or fourth week.

The antibody content of the serum in a given patient should be ascertained early and late in the illness. Diagnosis should be made in the presence of a rising titre of antibodies. Titres of 1:8 for agglutination and 1:20 for complement fixation are regarded as significant, but considerably higher titres are usually found at a late stage, i.e., weeks and even months after the onset.

No cross reactions with other members of the rickettsial group occur; serum from a case of "Q" fever will not agglutinate *Proteus* suspensions and do not contain cold agglutinins.

Treatment.—Prophylaxis is best achieved by immunisation (with formalised vaccine prepared from infected yolk-sac tissue) of individuals likely to be exposed to infection in stock yards, dairies, slaughter-houses, etc. Pasteurisation or boiling of milk is necessary in areas known to be infected: the former process may not be efficient. Transmission from patient to patient in a ward is unlikely so long as sterilisation of sputum and excreta is carried out. Quarantine and isolation are unnecessary.

Sulphonamides, penicillin and streptomycin have no appreciable effect on the course of the illness.

Chlortetracycline, chloramphenicol and oxytetracycline are effective. The illness itself is so variable in duration and severity, however, that it is difficult to judge the real value of chemotherapeutic treatment.

Chloramphenicol has been given orally in doses of 250 mg. 4-hourly, up to a total of 60 g. Smadel recommends oral administration of chlortetracycline or oxytetracycline in divided doses in a total dosage of 3 g. to 4 g. daily. Treatment is continued for some days after the fever has subsided.

Treatment with these antibiotics usually results in the fall of temperature to normal in a day or two and rapid resolution of the pulmonary signs and radiological pattern. A few cases may relapse shortly after treatment is stopped. These must be immediately re-treated with similar dosage régimes.

BRIAN MAEGRAITH.

G. INFECTIOUS DISEASES OF DOUBTFUL OR UNKNOWN ETIOLOGY

FOURTH DISEASE

INFECTIOUS ERYTHEMA

Synonyms —Megalerythema Epidemicum, Fifth Disease

A mildly infectious disease of which the aetiology and mode of transmission are unknown. With slight fever, a confluent rosy eruption appears on the cheeks, avoiding the circum oral region. The hot swelling, with its well defined edge, may suggest erysipelas. Discrete papules spread to the forehead and neck, on the next day they invade the trunk and limbs mainly the latter. The extensor surfaces and the buttocks are sites of predilection. The papules by confluence form patches, which may assume annular or gyrate patterns, spreading at the periphery and fading at the centres. The eruption disappears rapidly from the face and trunk, but may persist on the limbs for a week or more, and may recur as the result of irritation in a manner suggestive of urticaria. Complications are extremely rare. The incubation period is from 6 to 14 days. There is a slight polymorphonuclear leucocytosis. In contrast with rubella, cosinophilia may occur and plasma cells are scarce.

GLANDULAR FEVER

Synonyms —Infectious Mononucleosis, Monocytic Angina

Definition —An acute infection characterised by fever and adenitis with a great increase of mononuclear cells in the blood and the appearance of heterophile antibodies in the blood serum. Recovery is the rule, and complications are exceptional.

Ætiology —Glandular fever is probably a virus infection, but a small Gram-positive bacillus, *Listeria monocytogenes*, has on rare occasions been recovered from the blood. The route of invasion is unknown. Volunteers have been infected by blood transfusion and monkeys by emulsions of the swollen glands. Its prevalence is world wide. It usually occurs in the spring as small commensal outbreaks, but sporadic cases are not infrequent and occasionally more widespread epidemics appear. Children and young adults are chiefly attacked, males preponderating. The incubation period may vary from 5 to 12 days. Infectivity is slight and its duration short.

Symptoms and Types —In children and adolescents the onset is sudden, with fever and faucial injection. Stiffness of the neck, slight dysphagia or mild conjunctivitis may occur. Lymph glands, usually those under the upper half of the sternomastoid muscle, swell rapidly (*glandular type*). By the second or third day the glands may attain a considerable size. They are discrete and scarcely tender. The skin over them is not inflamed, nor is there any surrounding oedema. In some cases a definite membranous angina is present, and glandular tenderness is more pronounced (*anginose type*). Although the swelling is at first unilateral, the glands on the other side of the neck may enlarge in turn and minor or even primary swellings of the posterior cervical, axillary and inguinal groups may occur.

The adenitis is accompanied by sharp pyrexia, the fever being irregular, and ranging from 100° to 103° F, or even higher. Exceptionally a fleeting erythematous or rubelliform rash appears on the trunk.

The adenitis of glandular fever may not be limited to superficial glands or even obviously involve them. Paroxysmal cough, dysphagia and even pulmonary collapse may indicate mediastinal invasion. Vomiting and abdominal pain may accompany palpable swelling of the mesenteric glands. Appendicitis may thus be simulated.

Enlargement of the spleen usually slight but sometimes pronounced and less frequently of the liver, is common. Rarely hepatitis and jaundice develop after a week or longer, this may, on the evidence of the blood count and the Paul Bunnell test, be the only evidence of the infection. In some cases meningismus or a mild lymphocytic meningitis have been observed. These protean manifestations are very misleading.

D- The blood changes are distinctive but may be either transient or delayed. After a fleeting polymorphonuclear leucocytosis or, rarely, a neutropenia, there is a characteristic increase in the numbers of the mononuclear non granular cells. These may form 40 to 90 per cent of the total leucocytes instead of the normal 20 per cent. The cells are not of uniform type, as in acute leukaemias. Aberrant cells, which may in some respects resemble either large primitive lymphocytes, or large mononuclear or plasma cells, preponderate. There is general agreement that these cells are of the lymphoid series, they are sometimes seen in other diseases, but their presence in any number is diagnostic of glandular fever. The small lymphocytes may be diminished in number. The total leucocyte count is rarely more than 12 000 to 18 000 but may be 30 000 or more, occasionally there is leucopenia throughout the disease. The red cell count is not diminished.

Heterophile antibodies, which agglutinate the red corpuscles of sheep, appear in the blood serum. This is the Paul Bunnell reaction. It becomes positive with the appearance of the swollen glands. A titre of 1 in 100, or possibly less, is diagnostic of glandular fever. Appearing about the fifth day, it may persist for 1 to 4 weeks. Sometimes its appearance is delayed and repetition of the test is necessary. Its constancy is doubted by some observers. The distinctive antibodies are absorbed by ox red cells but not by guinea pig kidney. A similar reaction which may occur after the injection of horse serum is distinguished by absorption by both agents. A differential test, positive in a titre of 1 in 40, combines absorption and agglutination procedures.

The lymphadenitis is characterised by vascular congestion and by hyperplasia of the reticulo endothelium and germ centres which may be packed with cells like those in the blood. Similar cells occur in the spleen where they pack the sinuses infiltrate the trabeculae and ensheath the small arteries. They also penetrate the bone marrow.

The febrile stage of the disease may last for 10 days or a month and exacerbations of fever, with involvement of fresh glandular groups may occur. The glandular swellings subside more slowly than the fever. A subacute or relapsing type with sweats and irregular pyrexia, simulating Hodgkin's disease, has been described. The mononucleosis may be very transitory, or may persist for some time. Convalescence is slow.

In some cases, mostly adult, glandular fever may differ considerably from the disease as described above. There is a febrile course, very suggestive of enteric infection, with malaise, muscular pains, headache and perhaps epistaxis, but no marked soreness of the throat. Shivering or rigor may occur. Towards the end of the first or second week of fever, a scanty eruption of macules or of papules somewhat like those of typhoid fever, may appear on the trunk and perhaps the limbs. The diagnosis is established when glandular enlargement, usually less pronounced in this type supervenes in the third week or later, and the fever assumes a remittent form. At this stage a relative or absolute mononucleosis is most likely to be discovered and may be fleeting or very protracted. A membranous faucial inflammation may possibly now be found. The spleen may enlarge. Relapses may occur and the fever has been known to persist for many months, but recovery is still the rule. This variety is known as the typhoid type.

In some cases of glandular fever the Wassermann, or Kahn, reaction becomes temporarily positive. A misleading agglutination with typhoid 'O' antigen in low titres may also appear.

Very rarely petechial eruptions accompany glandular fever, the bleeding time is increased and platelet deficiency is present. This constitutes a rare purpuric type.

A striking feature of outbreaks of glandular fever is the occurrence of symptomless infections without overt clinical signs, the blood picture being typical and the Paul Bunnell test positive.

Complications—Suppuration in the glands is very rare. Otitis retropharyngea

abscess and laryngitis have been met with. A temporary albuminuria may occur and in some 6 per cent of the cases a benign hæmorrhagic nephritis. A more serious complication is the spontaneous rupture of a swollen, infiltrated and softened spleen which has been recorded on rare occasions. Sometimes atypical pneumonia or glycosuria occurs. Serous or lymphocytic meningitis is exceptional, as also are cerebral palsies and lesions of certain peripheral nerves. Myocarditis, sometimes with disturbance of the conducting system, is an occasional sequel.

Diagnosis—The clinical course is often so characteristic and the cervical adenitis so disproportionate to the faucial inflammation that suspicion of glandular fever should be aroused. In the more prolonged febrile form, fevers of the enteric group can be excluded by the blood count and the usual bacteriological and serological tests. In the membranous variety, diphtheria is excluded by absence of the Klebs Loeffler bacillus and of acute toxic symptoms, despite persistent membrane. D/D

Resemblance to rubella is sometimes close, but the differences in the blood films, and the Paul Bunnell test will decide. Sore throat, adenitis and a maculo papular rash may suggest secondary syphilis, and the possibility of a positive Wassermann reaction causes further confusion. The paroxysmal cough and leucocytosis may simulate whooping cough but the Bordet Gengou bacillus is absent, and the Paul-Bunnell test positive. Swelling of the salivary glands and even Mikulicz's syndrome have been reported in rare instances. In such cases, if authentic, mumps may be simulated. Vincent's angina may complicate glandular fever, but the occurrence of Vincent's organisms is now regarded as fortuitous. D/D

Acute leukaemia at its onset constitutes a very real difficulty, but the leucocytosis is usually far in excess of that of glandular fever and the cell type more uniform. The diversity of cells seen in glandular fever is lacking, anaemia is progressive and the issue fatal. Rarely lymphatic leukaemia of a very chronic type, with bouts of fever, adenitis, which is but slight, and moderate lymphocytosis is mistaken for the usual tardy convalescence from glandular fever. Hodgkin's disease is a much more chronic and progressive affection, here lymphocytosis rarely occurs, biopsy of a gland is the only certain diagnostic criterion. In acute infectious lymphocytosis the increase is in the small lymphocytes, and although an adenitis occurs, the Paul Bunnell test remains negative. Tuberculous adenitis has a greater chronicity, peri adenitis and suppuration with other signs of tuberculosis may be present. Septic adenitis induces a polymorphonuclear leucocytosis, and may suppurate. Agranulocytic angina is characterised by a low leucocyte count due to the disappearance of all granular cells. The differentiation of glandular fever with abdominal symptoms from appendicitis is based on enlargement of glands, spleen and liver, the blood picture and the positive Paul-Bunnell test.

Treatment—This is symptomatic. In the anginose form with severe symptoms neosarsphenamine intravenously has a decided palliative effect. In protracted cases injection of the blood serum of a convalescent may bring the disease to a termination. Excision of glands is unnecessary and should be avoided. Isolation for 7 days after the subsidence of the fever and glandular swellings is sufficient in the acute cases.

ERYTHEMA NODOSUM

Ætiology—Although this disease is a definite and easily recognisable clinical entity, it is still uncertain where it should be placed, when considered in relation to nosology or to ætiology. Formerly the favoured view was that the disease is a manifestation of acute rheumatism, but of this there is little or no evidence. It is now generally regarded as an allergic tissue response to various bacterial allergens. In some countries, especially those of Scandinavia, tuberculosis is the most frequent

underlying cause, in children it has been shown to make its appearance shortly after primary infection. In adults and adolescents it is more often a sequel of hæmolytic streptococcal infection of the naso-pharynx. A similar syndrome occurs in an early stage of Boeck's sarcoid and lesions, only distinguished with difficulty, are found in chronic meningococcal and chronic gonococcal septicæmia. A similar disorder has been recorded as a reaction to various drugs, including the iodides and the sulphamides.

It occurs more often in females than in males (according to Mackenzie, in the proportion of 5 to 1), and the majority of cases are found between the ages of 10 and 30 years. There is no seasonal incidence. It is much more common in hospital than in private practice; this and some other observations suggest that bad feeding or insanitary conditions may contribute to the incidence of the affection.

Pathology.—There has been demonstrated a widespread arteriolitis in the subcutaneous fat, resolving without suppuration or residual fibrosis.

Symptoms.—The symptoms consist of: (i) the local lesions, and (ii) certain constitutional changes.

(i) The local lesions are bilateral and occur chiefly upon the lower limbs; indeed in the great majority of the cases they are confined to these. When they appear on the arms they are most often found only in this situation, the patient is more often than not an adult and the general symptoms are less like rheumatic manifestation than is the case in the more common variety of the disease. The lesions are round or oval swellings, usually confined to the extensor aspect of the limbs, affecting the shin regions chiefly, and varying in size from a large pea to half an orange. There may be two or three only on each leg, or, in severe cases, the greater part of the extensor surface may be covered by them. They involve the subcutaneous tissue as well as the skin. They are very tender to touch. On their first appearance they are deep red in colour, later they become purple in hue, and still later they often show a definite ecchymotic appearance—giving rise to the name *dermatitis contusiformis*. In bad cases there is a good deal of associated œdema of the surrounding tissues.

(ii) The general symptoms include a mild grade of fever (not constantly present), joint pains, malaise and sore throat. But many cases occur in which the local skin condition, with pain and tenderness, covers the whole of the symptomatology. Constipation is common, and is sometimes severe. Radiographic examination of the chest will show in a proportion of cases some enlargement of the mediastinal glands, these are probably tuberculous or due to sarcoidosis. There is an initial leucocytosis and the erythrocyte sedimentation rate is raised, often considerably.

The course of the disease is from 2 to 3 weeks, but some mild cases get well

Children, Great Ormond Street, in 1885 Feer (Zurich) is generally accepted in Europe as having described cases about the same time as Swift

Ætiology—The clinical syndrome is generally ascribed to the effects of a widely diffused toxin which shows a predilection for the autonomic nervous system. It frequently follows an acute infection of the upper respiratory tract and less often gastro enteritis, either affording a possible portal of entry of a virus. Although not obviously infectious from case to case, small epidemics in localised areas have occurred in various parts of the world. This and a tendency to a seasonal incidence in spring and autumn offer obvious analogies with acute anterior poliomyelitis, and Mayerfer has described cases following this disease. Another theory favours a vitamin or other deficiency, but usually affected children have been well fed. Mercury poisoning has been blamed, especially in the U.S.A., following the use of teething powders containing calomel, but very many babies are given such powders and do not develop pink disease. For this reason allergy has been invoked to explain individual susceptibility, possibly to a wide variety of toxic substances. Recent claims in Australia for adrenal cortical insufficiency (and cure by common salt) have not been confirmed. The balance of opinion still seems to favour infection, probably by a virus, as the most likely cause. The disease occurs more especially in the temperate zones, affects the sexes equally and is almost limited to the period covered by the time of the primary dentition.

Pathology—Apart from various findings due to secondary infections, the specific morbid pathology of the disease is said to include minor microscopical changes in the medulla, cord and peripheral nerves. These consist of round celled infiltration, erythema and oedema. Some authorities maintain that even these changes are due to a non specific terminal infection, or to secondary nutritional depletion.

Symptoms—After a vague febrile onset, as intimated above, the infant fails to recover its previous vigour, and remains essentially miserable, with insomnia, muscular hypotonia, increasing loss of appetite and usually loss of weight. After a week or so some degree of stomatitis is commonly found, the child dribbles a lot, and just when the whole picture has been confidently ascribed to the effects of dentition the characteristic rash makes its appearance. This consists of three main features—a sweat rash, which may be present all over the trunk and proximal portions of the limbs, a curious "raw beef", puffy, non pitting oedema of the hands, feet and frequently of the nose, and eventually various degrees of furunculosis and pyoderma. The condition of the mouth deteriorates, teeth may be shed (and swallowed) photophobia is often marked and the child "burrows" in misery in the bedclothes constantly scratching and rubbing the hands and feet together. In severe cases the fingers and toes may be seriously bitten and the hair plucked out. Perspiration of a cold, clammy type is present and produces a "mousy" odour. Wasting and hypotonia become extreme, the child makes no effort to stand or walk and prolapse of the rectum may occur. Signs of affection of the nervous system are shown by a persistent tachycardia—which is constant and varies in degree according to the severity and state of the disease—the tendon reflexes are sometimes diminished or lost, and it may be possible to demonstrate a diminished sensitivity to pin prick. The disease is usually afebrile save for the effects of complications: the blood pressure is said to be raised, although the determination of this is a matter of some difficulty, and there is frequently a leucocytosis. Excessive excretion of mercury in the urine has been found by those favouring this form of toxic substance as a cause but there are chemical pitfalls here.

Complications—The upper respiratory tract infection may spread to affect the ears and, more seriously, to produce broncho pneumonia, which is always a menace because of the risk of aspiration with an infected mouth. Pyelitis is not uncommon. Various local infections of the skin are almost invariable in a case of ordinary severity. Sequelæ, however, are unknown and relapses seldom occur.

Diagnosis—There is no mistaking the disease once it is fully developed, and it obviously should be suspected whenever a young child appears to be seriously miserable for weeks at a time. Cases have been described with most of the classical symptoms, but without the rash or other skin changes. Tachycardia occurs in all cases, and unless the pulse-rate is 140 or more a diagnosis of pink disease should not be made with confidence.

Prognosis—In the absence of serious complications this is invariably good, and one attack confers immunity. Death is usually the result of some serious complication but occasionally is sudden after a period of increasing rate and irregularity of the pulse. It is suggested that in such cases the end is due to ventricular fibrillation.

Course—The whole clinical picture may be spread over 3 to 9 months, with some variation in the severity of the symptoms.

Treatment—Since the exact causation is unknown, preventive measures are impossible, and most of the treatment has perforce to be symptomatic. Good nursing is essential but hospitalisation is undesirable although often unavoidable for a period as the patient's mother is almost invariably worn out. Isolation in a cubicle is advisable. If weather permits the child's cot should be in the open air as much as possible, day and night. Silk or cotton clothing, frequently changed, is best, the eyes should be protected from glare and some restraint may be necessary to prevent quite serious self-infliction of damage to the skin. The diet should be adequate, well balanced, mostly liquid and offered cold, frequently and in small quantities. The troublesome anorexia can only be dealt with by skilful nursing. Deference to the deficiency theory of origin would indicate the administration of vitamin concentrates A, B, C and D, raw liver and some yeast preparation, such as Yestamin. Good results have been claimed for the injection of vitamin B₁ in massive doses, such as 1000 international units once a week. This has the merit of being a convenient way of treating an out-patient at a hospital. Whole vitamin B complex has also been used as well as individual constituents of the vitamin B series. Bellergal (1 to 3 tablets daily for several days) is believed to counteract the effects of the disease upon the autonomic nervous system. Dimercaprol (B A L) has been used by those favouring the poisoning by mercury theory. Some sedative is essential and a mixture of chloral and bromide, according to the age, is probably the most suitable and should be used freely. For the skin a tepid bath once or twice daily, followed by a methylated spirit rub and copious powdering with a fine talc (not starch) powder, will help to promote comfort. The irritation may be slightly allayed by calamine lotion or the use of menthol in paraffin (1 per cent) dabbed on at night. The mouth requires great care. Giving the child swabs soaked in hydrogen peroxide may be recommended, and actual inflammatory lesions should be dabbed with methyl violet solution (0.5 per cent. in water). Chemotherapy is of great value in most of the septic complications. During convalescence an iron tonic and a change to the seaside help to promote complete cure.

ALAN MONCRIEFF

"NON-SPECIFIC" OR ABACTERIAL INFECTION OF THE GENITAL TRACT

Ætiology and Prevalence—This condition, of which the cause is unknown, is undoubtedly a venereal disease, although it may be confused with other and less common forms of urethritis which are non-venereal. In prevalence it is second only to gonorrhœa among the venereal infections. The figures from the public clinics of England and Wales for 1952 show 11,552 cases of "non specific" urethritis in the male as compared with 15,510 cases of gonorrhœa. The infection often proves highly resistant to treatment and not infrequently persists indefinitely in latent form with the possibility of frequent clinical relapses. In some cases there are complications which may be local or metastatic.

Clinical Course.—*In the male*—In most cases the condition commences as a low grade urethritis with onset from 10 days to 4 weeks after intercourse, presenting with mucopurulent urethral discharge which is often scanty. Smears of the urethral discharge show pus cells and epithelial cells but no organisms, cultures grow no organisms or a few contaminants. One aspect of the urethritis in the male requires special mention. The urethral secretion is frequently so slight that the patient does not notice it. This may well account for the long incubation periods which are sometimes described, for the condition may be present for some time before it attracts attention. The true incubation period is probably about 10 to 14 days. It seems quite clear that in other cases the patient remains quite unaware of his condition which may come to light in the course of routine examination for some other reason, or through the development of a complication. Patients with asymptomatic infection may show no signs of the infection at the time of examination. In order to recognise the signs it may be necessary to examine the patients in the early morning before the first urine has been passed, if the urine has been held for 8 hours or more there is almost certain to be some secretion within the meatus and the urine will contain pus threads. Patients with asymptomatic infection are infectious to others by sexual intercourse and may at any time develop some complication.

In the female—The consorts of men with "non specific" urethritis nearly always show some evidence of infection which is presumed to be due to the same cause. Quite often there are no symptoms but if symptoms are present they are usually due to associated trichomonal vaginitis. The infection causes urethritis, cervicitis and, perhaps, proctitis. The diagnosis is difficult to make in the female because the evidence of urethritis is usually slight and the cervicitis has no characteristic features.

Complications—The local complications in the male and female are the same as those which affect patients suffering from gonorrhoea (see pp 66, 67) but they tend to be less acute. In particular ascending infection with inflammation of the uterine adnexa occurs in many cases in the female and recrudescence and relapse of tubal inflammation are very common. Sterility is a possible sequela. Metastatic complications are rare in the female.

Arthritis is the commonest metastatic complication. Polyarthritus is the rule, but occasionally only one joint is affected. The onset may be acute or subacute and where it is acute it is indistinguishable from that which may follow gonococcal urethritis. The joints of the lower limbs are most often affected, especially the knees, ankles and metatarso phalangeal joints, but any joints may be involved. The development of arthritis is associated with pyrexia of varying degree. The temperature is usually above 100° F., in severe cases it swings from 100° to 103° F or more and the patient appears very ill and becomes cachectic. Tachycardia with pulse rate of from 120 to 150 to the minute is found in some cases. The erythrocyte sedimentation rate is much raised being more than 100 mm in 1 hour (Westergren) in many of the cases. In less severe cases with recurring attacks constitutional symptoms may be slight or absent. The attack of arthritis is usually self limited and is likely to subside spontaneously after periods which vary from 1 to 12 months. Even in severe cases ultimate clinical recovery may be complete. Recovery may be permanent, but some patients are very prone to recurrent attacks of arthritis, and ultimately chronic arthritis or residual deformities may result. In the main the late effects are of three kinds.

(1) Multiple attacks without residual joint damage—The later episodes of arthritis are sometimes related to sexual intercourse or to fresh attacks, or relapses, of urethritis, sometimes they occur without evident precipitating cause. The intervals between recurrences are highly variable and years may intervene. Each recurring episode of arthritis usually lasts up to 2 months. As with the initial attacks the distribution of the arthritis is not necessarily characteristic, for, although the knees and feet are usually affected, some patients show more generalised polyarthritus with involvement of small joints of the hands and wrists.

(2) Residual deformities of the feet—The commonest of these is the painful calcaneal spur in association with the posterior attachment of the plantar fascia. Pes planus is sometimes a residual deformity, in other cases pes cavus occurs and may be associated with fixed dorsiflexion of all toes at the metatarso phalangeal joints, giving multiple hammer toe deformities. The hammer toes, and also lateral deviation of the toes at the metatarso phalangeal joints may occur without pes cavus.

(3) Ankylosing spondylitis—The usual course is an initial polyarthritis followed later by spinal stiffness. In the early stages low back pain is associated with radiographic blurring of the sacro iliac joint and it is only later that the poker back and bamboo spine develops.

Acute attacks of arthritis may be associated with crusted lesions on the soles of the feet or perhaps widespread over the body, known as *keratoderma blenorrhagica* and with erythematous and desquamatory areas on mucous membranes, particularly on the glans penis and in the preputial sac, where the condition is called *balanitis circinata*.

Iritis also occurs as the result of this infection. It is occasionally found in the course of an attack of arthritis but more commonly appears independently, perhaps after the lapse of months or years from the original infection. It shows a strong tendency to repeated relapses.

Conjunctivitis—Inflammation of the conjunctiva as the result of direct contamination probably occurs in some cases, notably in the newly-born. More commonly however, the infection is blood borne and then nearly always involves both eyes. It is usually mild but occasionally severe and tends to resolve quickly, although relapses are not uncommon in severe cases.

The triple syndrome of primary non gonococcal urethritis of venereal origin, polyarthritis and bilateral conjunctivitis is comparatively uncommon. It is very rare among women. For inadequate reasons it is often called *Reiter's syndrome*. There appears to be an almost identical syndrome associated with dysentery, in which the primary focus of infection is in the bowel and not the urethra, but this is not known to occur in this country. Reiter, in 1916 described a single case of what was probably the dysenteric syndrome. The syndrome associated with venereal urethritis was fully described by Benjamin Brodie in 1818 and by others during the intervening period.

Treatment—The urethritis is apt to be resistant to treatment and is prone to relapse after apparently successful treatment. Some cases respond to sulphonamides by mouth and some to streptomycin given intramuscularly in dosage of 1 to 2 g daily for 5 days. In general, however, the results of such treatment have been disappointing. Lyall (1953) recently claimed excellent results by combining these two drugs. He gave 1 g of streptomycin intramuscularly followed by 6 g of sulphathiazole daily for 5 days. The newer antibiotics all have some effect. According to Harkness (1953) the best results are obtained with oxytetracycline by mouth. He gave 500 mg 6 hourly for 4 days and claimed success in 86.5 per cent of cases, as compared with 63 per cent after similar dosage of chlortetracycline and 36 per cent with chloramphenicol.

Assessment of the value of any form of treatment for arthritis due to this cause is difficult. Any treatment which continues over 3 to 4 weeks will often coincide with spontaneous remission. The various antibiotics and sulphonamides appear to be ineffective. Artificial fever therapy produces temporary improvement, perhaps due to adrenal stimulation. Both corticotrophin and cortisone in sufficient dosage are capable of suppressing temporarily the various arthritic, ocular and cutaneous manifestations of the disease. The amount of hormone required appears to be proportionate to the severity of the inflammatory process. It may be that these hormones will provide a rational method of management of these cases by maintaining suppression of symptoms and signs of the condition until spontaneous remission occurs.

TROPICAL EOSINOPHILIA

Synonyms.—Tropical Pulmonary Eosinophilia, Eosinophilic Lung, Tropical Eosinophilic Asthma

Definition.—An acute or relapsing condition associated with loss of weight, cough and pulmonary signs and symptoms resembling asthma. Pulmonary radiograms usually show a picture of increased transverse striations and discrete soft mottling, sometimes closely resembling tuberculosis. Most cases respond rapidly to arsenical therapy.

Ætiology.—The cause is unknown. Present opinion inclines to viral infection. Worm infestations and pulmonary invasion by mites were at one time suspected as possible causal factors, but are now excluded. The condition occurs mostly in hot, moist coastal regions. There is no seasonal incidence. It was first observed in the indigenous population of India and has since been reported in most Asiatic races and in increasing numbers of Europeans living in India, the Far East and Africa.

It occurs most commonly in the age group 21 to 40 years, except in some parts of India, where children are most frequently affected. It has been reported in children under 6 years of age and in adults over 60 years of age. Sex and occupation do not seem to be ætiological factors.

Pathology.—The condition is not fatal. The only morbid anatomical evidence available was obtained from patients who died of some other cause. In these cases, pulmonary changes resembled those of viral pneumonitis, as indicated by the radiographic picture. There is usually a considerable leucocytosis and always an increase in absolute numbers of eosinophils. Details of the blood picture are given below. Sternal marrow smears show an increase in eosinophilic elements.

Smears of sputum show epithelial cells and clumps of eosinophils. The bacteriological content is non specific. Mites belonging to the family *Tyroglyphidae* may sometimes be found in centrifuged deposits of sputum digested in 4 per cent sodium hydroxide. They are not specific to the syndrome.

Symptoms and Signs.—The clinical picture varies considerably from patient to patient.

Pulmonary signs and symptoms.—The commonest complaint is coughing, usually in nocturnal paroxysms lasting from a few minutes to an hour. There may be little or no coughing during the day.

Paroxysms often occur several times during the night and may be of considerable violence, forcing the patient to sit up in bed in acute respiratory distress closely resembling an asthmatic attack, except that bronchial spasm is not always present and the dyspnoea is not always expiratory in type. *Status asthmaticus* has been reported.

A sense of constriction of the chest is common during and for some time after a coughing paroxysm. There may also be some aching pain in the sternal region or epigastrium, persisting for some time after the coughing.

Coughing is accompanied and succeeded by expectoration of mucoid or mucopurulent sputum, sometimes in considerable quantities. The sputum may be streaked with bright blood, occasionally there may be small hæmoptyses, especially immediately after a paroxysm. In some cases sputum may be coughed up throughout the illness, in others it appears only during and for a short time after the coughing paroxysm.

Chest signs may be minimal or absent, even when the clinical picture is severe. In most cases, however, during coughing and for some time afterwards, scattered sibilant or sonorous rhonchi and occasionally coarse crepitations may be heard in both lungs, especially over the bases. Signs of emphysema are common.

Sweating is usual during or shortly after the paroxysm and is sometimes profuse.

The paroxysms of coughing lead to disturbance of sleep, severe insomnia and progressive fatigue. Most patients rapidly lose weight.

Pulmonary radiograms.—In all active cases, there are pulmonary radiographic changes. The hilar shadows are usually irregularly enlarged and blurred. The lung fields are transversely crossed with fine irregular branching striations best seen in the mid-zonal regions. Mottled shadows present as discrete, soft, rounded and sometimes ill-defined areas up to 3 cm. in diameter. There may be few or many and the numbers of spots present vary considerably from patient to patient.

The radiological pattern is usually bilateral and most commonly basal in distribution. The apices are usually clear but are occasionally involved. Unilateral changes have been reported. There may be no mottling. Very occasionally the latter may be the only sign. Patchy emphysematous changes are very common in longstanding cases.

The transverse striation and mottling usually disappear after successful treatment and return during relapses.

The appearance of the shadows varies from time to time and it is not always easy to correlate the pulmonary radiographic picture with the prevailing clinical respiratory picture or eosinophilia. On the whole, the shadows are more prominent in early acute cases. There may sometimes be associated areas of consolidation or basal pleural thickening.

The blood.—The white cell count ranges between 10,000 and 100,000 cells or more per c.mm. Eosinophils constitute 25 per cent. or more of the total cells; counts of 80 per cent. or higher are common in acute cases. Other cells are usually present in normal numbers.

The white cell count and numbers of eosinophils vary considerably from time to time in a given patient. Intercurrent infection may affect the picture by temporarily raising the number of polymorphs and reducing the eosinophils. The eosinophils are normal in appearance. The sedimentation rate is increased: i.e., of the order of 20 to 60 mm. per hour. It returns slowly to normal after treatment.

Other presenting signs.—Some patients do not complain of coughing or other respiratory disturbances. In these, the chief complaints are likely to be progressive lassitude and loss of weight, and sometimes inexplicable nocturnal sweating.

The patient is usually thin and may be emaciated. He is usually anorexic. Insomnia, especially when associated with nocturnal paroxysms of coughing, may lead to a desperate desire for rest and sleep. It is sometimes this helpless feeling of weariness that drives the patient to the doctor.

There may be an irregular low-grade intermittent fever in acute cases, the peaks of fever occurring in the evening. Many cases, however, even when suffering from severe pulmonary disturbances, remain afebrile. There are no circulatory disturbances. The heart is unaffected and the pulse-rate is normal, except during paroxysms when it may be fast. The lymph glands and spleen are not enlarged.

Course.—The condition is not fatal. It may last for years, with alternating periods of exacerbation and remission. Signs and symptoms usually develop gradually over months and sometimes years. On the other hand in some cases the development may be rapid.

Spontaneous recovery is common after a few months or years. Recurrences are rare after more than 2 years of quiescence.

Response to treatment is usually rapid. Recurrences are common but respond well to further treatment. A few cases are refractory to treatment but even these tend to recover eventually.

Diagnosis.—The diagnosis may be obvious from the clinical picture of nocturnal coughing paroxysms and the high eosinophil count. The lung signs, especially when associated with evening fever and sweating, may be easily confused with those of tuberculosis. Points of difference are the usual absence of apical signs and the common

mid-zonal and basal distribution of signs in the eosinophilic case, and the characteristic combination of striation and mottling in the pulmonary radiogram. The mottling in tuberculosis is usually distributed more widely over the lung fields and the individual shadows are harder and more clearly defined.

Difficulty may be experienced in distinguishing tropical eosinophilia from bronchitis and bronchiectasis or from allergic bronchial asthma. In the latter case, the patient suffers from expiratory dyspnoea and coughs after relief, in tropical eosinophilia there is often no expiratory distress and cough occurs during, as well as after, the paroxysm.

The radiographic picture may be mistaken for that of Loeffler's syndrome in which, however, the lung changes are transitory and the upper respiratory tract is usually involved.

The eosinophil count is the conclusive point in diagnosis. In the diagnosis of the individual case, the number of eosinophils per c mm should exceed 3,000, and the total white count 10,000 cells per c mm. Figures of this order associated with pulmonary symptoms confirm the diagnosis. It must be remembered, however, when dealing with members of the indigenous population in tropical countries, that white cell counts of 10,000 with an eosinophilia of 10 to 12 per cent are quite common. When eosinophilia occurs in asthma, hay fever, etc., it is never of the order seen in tropical eosinophilia. This is true of most parasitic infections which should be identified by discovery of the causative agent. A few worm infestations may produce a very high eosinophil count and may also be temporarily associated with pulmonary signs and symptoms. It is therefore most important to exclude these infestations as far as possible. Loeffler's syndrome is characterised by the presence of a very high percentage of eosinophils in a relatively low total white count.

Treatment.—Most cases react rapidly to arsenicals. The best results are obtained by parenteral treatment. Dosages of representative drugs are given below.

Novarsenobillon 300 to 600 mg given intravenously. One dose at weekly intervals for 6 to 8 weeks.

Acetylarsan 3 to 5 ml intramuscularly once weekly for 6 to 8 weeks. (Each ml contains 20 mg arsenic.)

Stovarsol Gr 4 twice or thrice daily for 7 to 10 days.

Chlortetracycline may be given to the few cases which do not respond to arsenicals.

Dosage 500 mg orally three times daily for 7 to 10 days.

There may be exacerbation of symptoms, with fever and increase of eosinophils after the first or second injection of arsenicals, or after the first few days on chlortetracycline. In some cases painful nodular swellings resembling those of erythema nodosum may appear at about the same time, especially on the limbs. Treatment should be continued in spite of these reactions.

In the majority of cases treatment with arsenicals is followed by almost immediate response. There is a rapid fall of total white cell numbers due to reduction in eosinophils. Normal white counts may be reached in 6 weeks from the beginning of treatment, but the eosinophils may remain at 10 to 15 or even 20 per cent for some time longer. In treatment with chlortetracycline no improvement may be noted at all for the first week. After this, progress is rapid.

The radiographic pattern in early cases responds remarkably, often disappearing within a month. This effect is of considerable diagnostic importance.

Relapses, with return of clinical signs, the high white cell count, eosinophilia and radiographic pattern, occur in about 10 per cent of cases within 2 years of treatment. Most relapses respond rapidly to arsenical therapy or chlortetracycline.

A few cases may continue to relapse after several courses of treatment. Even in these cases, however, recovery may be anticipated after a few years.

BRIAN MAEGRAITH

SECTION III

DISEASES DUE TO METAZOA

A. DISEASES DUE TO TREMATODES OR FLUKES (DISTOMIASIS)

PARAMPHISTOMIASIS

Definition—An invasion of man with amphistome flukes of the family *Paramphistomidae*. Two of these parasites are known *Watsonius watsoni* (*Cladorchis watsoni*)—L. 8 to 10 mm \times 4 to 5 mm, Ova, 120 to 130 \times 75 to 80 μ . The parasite has a reddish yellow colour when fresh and inhabits the duodenum and upper part of the small intestine. *Gastrodiscus hominis*—L. 5 to 8 mm \times 3 to 4 mm, Ova, 150 \times 72 μ . The parasite has a large posterior disc by which it attaches itself to the mucous membrane of the bowel, it occurs in the caecum and colon.

Symptoms—Diarrhoea, with loose bilious stools in the case of the former parasite and intestinal disturbances with diarrhoea in the latter. The eggs of both parasites are found in the faeces.

Treatment—Carbon tetrachloride (3 ml) is probably specific.

FASCIOLIASIS

Definition—An invasion of man and other animals with flukes of the family *Fasciolidae*. Several of these are known.

(1) *Fasciola hepatica* (*Distoma hepaticum*) the common liver fluke inhabiting the bile ducts of sheep and other mammals. L. 20 to 30 mm \times 8 to 13 mm. The ova are operculated and oval, measuring 130 to 145 \times 70 to 90 μ . From them miracidia emerge which develop into sporocysts, rediae and cercariae in snails of the species *Limnaea truncatula*, later the cercariae encyst on grass stems and are subsequently eaten.

Symptoms—Man is occasionally infected, light infections may be discovered accidentally during stool examinations, while severe cases may succumb to secondary cholangitis and liver abscess. In sheep the disease produces liver rot, which may be fatal.

Treatment—Good results are reported following a course of emetine injections. Carbon tetrachloride is effective in sheep and has been favourably reported on in human cases, it is contraindicated where there is calcium deficiency.

(2) *Fasciolopsis buski* (*Distoma crassum*)—L. 30 to 70 mm \times 12 to 14 mm, Ova 120 to 130 \times 77 to 80 μ .—This giant fluke is found in China, Borneo, Malaya, Assam, Bengal and other regions in the East. It inhabits the small intestine, particularly the duodenum, producing focal lesions. The immature eggs are voided in the faeces. The miracidium matures in 3 to 7 weeks and escapes through the operculum. It enters certain snails (*Planorbis canosus*, *Segmentina nitidella* etc.) and develops into sporocysts and rediae which generate cercariae, the latter encyst on water plants—water caltrop and water chestnut—man becoming infected by eating the corms. The cercariae encyst in the duodenum and mature.

Symptoms—The incubation period is 3 months. Initial symptoms include hypogastric pain, acid dyspepsia relieved by food, and diarrhoea. Later, asthenia, oedema of the face and extremities, ascites and dry, harsh skin develop.

Diagnosis—The condition may simulate gastric ulcer or typhoid, and is diagnosed by finding the ova in the stools

Treatment—PROPHYLACTIC—Consists of cooking water caltrops and water chestnuts and sterilisation of night soil

CURATIVE—Carbon tetrachloride (3 ml), hexylresorcinol (1 g), betanaphthol (gr 5 to 10) and emetine are said to be specifics

PARAGONIMIASIS

Paragonimus westermani (*Distoma westermani*, *D. ringersi*)

Definition—An invasion of the pulmonary tissues by the lung fluke, a member of the family *Troglorematidae*

Ætiology—Paragonimiasis occurs endemically in the Far East, especially Formosa, Japan, Korea and China. The adult flukes (7.5 to 12 mm \times 4 to 6 mm) form cysts in the lung, where the broad, oval, immature, operculated ova (80 to 118 \times 50 to 70 μ) escape via the bronchi and appear in the rusty brown sputum. They are also found in the faeces (40 per cent). After attaining maturity the miracidium emerges, and invades a melanoid snail, especially *Melania libertina*, where it forms sporocysts, rediae and, later, cercariae which encyst in the gills, liver and muscles of certain freshwater crabs or cray fish—*Potamon obtusipes*, etc. If eaten by man the adolescaria emerges in the duodenum and migrates via the peritoneal cavity and diaphragm into the lung.

Pathology—Host reaction results in cyst formation around the fluke, which generally communicates with adjacent bronchi into which the eggs and anchovy-sauce cyst content are discharged. Pulmonary lesions consist of fibrosis, cystic dilatation of the bronchi, broncho pneumonia and tubercle like abscesses. Similar cysts may involve the intestinal mucosa, bile ducts, peritoneum, pleura, brain, spleen and liver.

Symptoms—These are divided as follows: (1) *General*, which include adenitis and skin ulcerations; (2) *Thoracic*, characterised by cough, brownish or reddish purulent sputum and hæmoptysis with physical signs of broncho pneumonia, pleural effusions or bronchiectasis; (3) *Abdominal* with involvement of the liver, spleen, pancreas or intestine; if the latter, there is diarrhoea with eggs in the faeces; (4) *Cerebral*, with Jacksonian epilepsy, hemiplegia, monoplegia, aphasia and eye symptoms. Headaches, loss of memory and insomnia may be present.

Diagnosis—This is made by finding ova in the sputum or faeces. The complement fixation reaction may be of assistance. Eosinophilia is also present.

Prognosis—Brain cases are fatal, and the outlook is bad in all severe infections.

Treatment—Abstinence from eating raw freshwater crab or cray fish prevents the disease. Emetine and tartar emetic temporarily relieve pulmonary symptoms, but cures are doubtful (Faust).

CLONORCHIASIS

Definition—An invasion of the bile ducts of man and other mammals with trematode parasites of the family *Opisthorchidae*, occurring in Japan, Korea, China, etc.

Ætiology—*Clonorchis sinensis* (*Distoma sinense*, *Opisthorchis sinensis*, etc.) is a spatulate fluke, measuring 10 to 20 mm \times 2 to 5 mm. Its yellowish brown ova are oval, possess a well marked operculum and measure from 27.3 to 35.1 \times 11.7 to 19.5 μ . Viable eggs are ingested by certain bithynid snails (*Parafossarulus striatulus*, *Bithynia fuchsiana*) and the miracidia penetrating the soft parts, form sporocysts, rediae and

finally cercariae, which escape, and encyst in the flesh of certain freshwater fish of the family *Percidae*, *Gobiidae* and *Anabantidae*. When the mammalian host eats infected fish the adolescaria escapes in the duodenum and directly invades the bile ducts, especially the left, owing to its straighter course.

Pathology.—Initially infection leads to primary proliferation of the biliary epithelium and thickening of the duct wall; later this becomes greatly thickened, and finally cirrhosis of the liver with destruction of the parenchyma results (Faust). The pancreatic duct is sometimes involved.

Symptoms.—Mild cases may be symptomless, but the heavier infections show anorexia, epigastric pain, hepatomegaly, diarrhoea, wasting, jaundice, oedema and ascites. **Diagnosis.**—This is made by finding the eggs in the faeces.

Prognosis.—This is dependent on the intensity of the infection; heavily infected cases occasionally die, but mild and moderate ones invariably survive unless some intercurrent disease develops.

Treatment.—Prevention lies in the cooking of freshwater fish before consumption. Tartar emetic intravenously possibly reduces the number of worms, while gentian, crystal and methyl violet reduce the intensity of infection as measured by the egg-cell count. Gentian violet is given as a keratin-coated pill ($2\frac{1}{2}$ grains) thrice daily after meals for 10 days; for intravenous use 40 ml. of an 0.5 to 1.0 per cent. solution is injected every other day; not more than 6 g. is advised (Faust).

When the liver is enlarged and tender, bile drainage may be accelerated by concentrated magnesium sulphate fed through a duodenal tube left *in situ* for several days. It decreases intra-biliary pressure and absorption of toxic material, but does not cure.

HETEROPHYIASIS

Definition.—Infection with flukes of the family *Heterophyidae*. Three genera occur in man.

(1) *Heterophyes heterophyes* (*Distoma heterophyes*, etc.).—A minute intestinal fluke infesting man, the dog, cat, etc., in Egypt, measuring 1.0 to 1.7×0.3 to 0.4 mm. The oval, light-brown, operculated ova measure 28 to 30×15 to 17μ . The first intermediate host is the brackish-water snail, *Pirenella conica*, and the cercariae encyst in mullet (*Mugil cephalus*), the ingestion of which causes infection.

(2) *Heterophyes hatsuradai* differs morphologically in the great size of its acetabulum, etc.

(3) *Metagonimus yokogawai*.—This pear-shaped fluke measures 1 to 2.5×0.4 to 0.75 mm., while its eggs closely resemble *H. heterophyes*, measuring 26.5 to 28×15.5 to 17μ . The life cycle passes through *Melania libertina* and allied molluscs, the cercariae encysting in the edible fish, *Plectoglossus altivelis*.

(4) A number of other heterophyid flukes, including *Monorchotrema taichi*, *M. taihoku*, *Diorchitrema pseudocirrata* and *H. brevicaca*, have been recorded by Africa and Garcia from Manila.

Pathology.—The flukes become attached to the intestinal mucosa by their suckers, inducing mild inflammatory reactions and eosinophilia.

Symptoms.—Mild digestive disturbances and diarrhoea with blood in the stools may result in severe infections. Often the condition is symptomless, the diagnosis being made by finding ova in the faeces. In their cases in Manila, Africa and Garcia have described a condition of cardiac heterophyidiasis, resembling cardiac beriberi, associated with sclerosis of the mitral valves and fibrosis of the myocardium; heterophyid ova were demonstrated in the local lesions.

Treatment.—Carbon tetrachloride, betanaphthol and emetine injections are said to be efficacious in eradicating the infection. To find the parasites, the stools must be strained through muslin.

SCHISTOSOMIASIS (BILHARZIASIS)

Definition—Invasion of man with blood flukes of the family *Schistosomidae*. Three species are well known—*Schistosoma hæmatobium*, *S. mansoni* and *S. japonicum*. More rarely man may be affected by *S. bovis* and *S. matthei*. **Life cycle**—The parasites inhabit the portal veins and their tributaries, depositing ova in the hollow viscera, whence they escape via the urine or faeces, on contact with water miracidia emerge, invade the appropriate molluscan intermediary, in which sporocysts and cercariæ develop (Miyairi and Leiper). The latter invade the skin and find their way to the portal system, where the schistosomulæ mature. The tuberculated male, originally a flattish fluke, has become rounded by inrolling of its edges to form the gynæcophoric canal, in which the threadlike female lies. Both sexes have an anterior, prehensile sucker and a posterior, suctorial sucker by which the worm maintains its position against the portal blood-stream.

S. hæmatobium (*Bilharzia hæmatobia*) occurs in Africa and parts of Western Asia, etc (♂ 10 to 15 mm × 0.8 to 1.0 mm, ♀ 20 mm × 0.25 mm). The ova have a sharp terminal spine and measure 120 to 160 × 40 to 60 μ . The intermediary hosts vary considerably, being *Bullinus contortus*, etc., in Egypt, *Physopsis africana* in Natal and Rhodesia, and *Planorbis metidjensis* in Portugal. *S. mansoni* is found in Africa, South America, etc (♂ 10 to 12 mm × 1.0 to 1.2 mm, ♀ 12 to 16 × 0.16 mm). The ova have a lateral spine and measure 140 to 165 × 60 to 70 μ . The intermediary host is *P. bosnyi* in Egypt, *P. pfeifferi* in West and East Africa and *P. guadeloupensis* in the West Indies and South America. *S. japonicum* is confined to the Far East—Japan, China, Formosa and the Philippines (♂ 12 to 20 mm × 0.5 to 0.55 mm, ♀ 15 to 26 mm × 0.3 mm). The ova possess a lateral knob and measure 100 to 110 × 55 to 65 μ . The intermediate hosts are *Katayama nosophora*, *K. formosana* and *Oncomelania lupenensis*.

Pathology.—In *S. japonicum* and *S. mansoni* the worms are found in the portal system, especially its mesenteric branches, ova being deposited in large numbers in the colon and liver, and to a lesser degree in the small intestine, mesenteric glands, stomach, pancreas and rarely the spleen. In *S. hæmatobium* they wander still farther afield via the inferior hæmorrhoidal plexus into the pelvic plexuses of veins, especially the vesical, prostatic and uterine, eggs are deposited in the bladder, prostate, seminal vesicles, urethra, the lower third of the ureter, cervix and vagina. These plexuses communicate with the inferior vena cava, in consequence stray ova filter out into the lungs rather than the liver. Apart from toxic effects and suctional trauma produced by the schistosomes themselves, the egg deposits cause considerable local inflammatory reaction, at first giving rise to small pseudo-tubercles initially composed of giant cells, eosinophiles and round cells, later these disappear or are replaced by whorls of fibrous tissue in which degenerated and calcified eggs are found. The characteristic papillomata form as a combined result of irritative downgrowth of epithelium produced by toxic substances liberated from worms and ova, and submucous cellular accumulations pressing the mucosa upwards from below.

Special pathology.—*S. japonicum* and *S. mansoni* produce various colonic lesions including round, yellowish, submucous, pseudo tubercles bilharzial colitis and papillomata, which may slough off, leaving round ulcers. All these lesions may be visible with the sigmoidoscope. In addition, marked fibroid thickening and contractions of the bowel wall, mesentery and omentum sometimes occur. Periportal cirrhosis of the liver, which may or may not be associated with bilharzial splenomegaly, is met with. Other lesions include rectal papillomata, prolapse of the rectum, perineal granulomata and ischio-rectal fistulae. In *S. mansoni* egg deposits in the spinal cord may produce myelitis, and granuloma of the brain simulating cerebral tumour is recorded in *S. japonicum*. In *S. hæmatobium* vesical lesions are dominant, but in

addition there may be involvement of the ureters (lower third), chronic fibrosis of the prostate and seminal vesicles, bilharzial infiltration of the cervix, vagina and perineal tissues with sinus formation, and granulomata of the penis and vulva. In the bladder the earliest lesions are minute petechiae and round, yellowish, pseudo-tubercles studding its surface; later, papillomata and ulcers may develop, while chronic fibroid thickening and the so-called "sandy patches" are very characteristic of the chronic stages with calcified eggs. These lesions are demonstrable cystoscopically. Pulmonary fibrosis associated with egg deposits is not uncommon, but involvement of the colon and liver is minimal.

Symptoms.—Three stages can be recognised: (1) invasive; (2) toxic or anaphylactoid; (3) localised disease (a) early, (b) late.

(1) *Invasive*.—The entry of cercariae may give rise to transient rash and local irritation lasting 24 to 48 hours (Kabure disease).

(2) *Toxic or anaphylactoid*.—Within 2 to 8 weeks a clinical syndrome may appear, characterised by urticaria and an intense eosinophile leucocytosis; in addition there may be rigors, abdominal pain, enlarged tender liver and spleen, dyspnoea, bronchitis, anorexia, diarrhoea and fever, lasting a few days to several weeks; the severe cases often simulate typhoid. This stage is most often described in *S. japonicum* (Katayama disease), but it also occurs in *S. mansoni* and *S. haematobium* infestations. Fulminating cases due to hyperinfection with *S. japonicum* may die from toxæmia before ova appear.

(3) *Localised disease*.—Local features dependent on egg deposition in the bladder or colon are not generally apparent for 3 to 9 months after infection. In *S. haematobium* early symptoms include scalding or frequent micturition, penile, perineal, suprapubic or loin discomfort or pain, and terminal hæmaturia, the blood being bright red and increased by exercise. At this stage the prostate may be congested and tender, cystoscopic examination shows the characteristic yellow, round pseudo-tubercles, and the urine contains leucocytes, erythrocytes and terminal-spined ova which may also appear in the faeces (40 per cent.). For years intermittent hæmaturia may be the only clinical manifestation, the subsequent course depending on such complications as carcinoma, cystitis and renal involvement. In *S. mansoni* localised features may be absent or a chronic bilharzial dysentery may develop, characterised by colicky abdominal pain, the passage of blood and mucus, and tenesmus. Between attacks there is rectal discomfort, but the stools are solid, and coated with mucus, which may contain the characteristic lateral-spined ova. Later periportal cirrhosis and splenomegaly with ascites, etc., may supervene. In *S. japonicum* similar dysenteric symptoms are present. The chronic stage with cirrhosis and splenomegaly is characterised by weakness, emaciation, pallor, secondary anaemia, dilatation of the abdominal veins and finally ascites and liver insufficiency.

Complications.—In *S. haematobium* there may be chronic nephritis or hydro-nephrosis due to backward pressure, or septic cystitis with pyonephrosis or ascending pyelonephritis. Carcinoma of the bladder, penis or vulva may also ensue, while bilharzia papillomata and vesical calculi are not uncommon. In *S. japonicum* and *S. mansoni* hepatic cirrhosis with or without splenomegaly may supervene.

Diagnosis.—In the early toxic or anaphylactoid stage the diagnosis may be suggested by the intense eosinophilia and confirmed by the cercarial complements fixation reaction. In the localised stage the diagnosis is generally made by finding ova in the excreta, but the complement-fixation reaction and the cystoscopic or sigmoidoscopic findings often prove of considerable value. The small nodules or pseudo-tubercles seen in the bladder or pelvic colon and rectum during instrumental examination in the early stages of the disease are yellowish in colour while the ova are living and become whitish when they die and calcify. In examining for *S. mansoni* or *S. japonicum*, the mucus covering of the stool should be selected, and in *S. haematobium* the last few millilitres of urine passed; several examinations may be

necessary and eggs may be found in scrapings from the bowel wall obtained with a blunt curette during sigmoidoscopy, when ordinary faecal examinations are negative

Concentration of ova by sedimentation of the stools with 25 times their volume of 0.5 per cent glycerin in water is sometimes helpful

Prognosis—The prognosis is bad only in patients continuously exposed to infection, or in late cases when hepatic or renal insufficiency, septic infection or carcinoma has supervened. Otherwise the results of treatment, with full courses of tartar emetic, are satisfactory, two or even three courses of treatment are sometimes necessary, especially in *S. japonicum* infestations

Treatment—**PROPHYLACTIC**—This consists in curing the disease in man, in preventing excretal contamination of water, in destruction of snail vectors and in avoiding contact with infected water

CURATIVE—Three trivalent antimony compounds, tartar emetic, Antihomaline and stibophen (Fouadin), as well as emetine hydrochloride, exert a specific lethal action on the adult schistosome. During treatment rest in bed is advisable, especially if complications exist, but in Egypt and other endemic areas generally ambulatory treatment is alone practicable

(1) *Tartar emetic*, first successfully introduced by Christopherson, is given intravenously in 10 ml of saline every second day, commencing with gr $\frac{1}{2}$ and increasing by gr $\frac{1}{4}$ until a maximum of gr 2 is attained. The solution should be freshly prepared each day, and the total course for the adult should be at least gr 30. The drug kills the schistosomes, and viable ova completely disappear from the excreta in about 10 to 14 days owing to the degenerative effects exerted on the yolk glands and ovaries of the female worms. Relapses are due to gradual recovery of the surviving female worms and restoration of their egg laying function. Cough, vomiting and toxic muscular pains may follow its administration, but the drug is generally well tolerated except in cases complicated by hepatic cirrhosis, renal involvement, sepsis, etc. Great care must be taken not to inject any tartar emetic solution into the tissues, as severe inflammation and necrosis result. Recently, intensive mass treatment with sodium antimonyl tartrate has been advocated, a total dose of 12 mg per kg body weight being given in 6 intravenous injections in 2 days (Alves and Blair). This intensive course is not considered to effect sterilisation of the infection as frequently as the classical longer course

(2) *Stibophen (Fouadin)* (antimony pyrocatechol disulphonate of sodium) should be given in an all glass syringe in 6.3 per cent solution, the ordinary course consists of 40 ml administered in 9 intramuscular injections extending over a period of 15 days. Even when twice this amount of drug is given, i.e., 80 ml, the results are not as satisfactory as those obtained with tartar emetic. Another useful trivalent antimonial is Antihomaline, given intramuscularly in doses of 2 ml (0.01 g metallic antimony) on alternate days for up to 20 doses. Results with this drug are not as good as with tartar emetic

(3) *Emetine hydrochloride* in a dosage of gr $1\frac{1}{2}$ daily for 10 days is advocated intravenously (Tykhalas). Though emetine undoubtedly kills schistosomes, this treatment is dangerous owing to toxic effects on the myocardium and is rarely used

An entirely new drug known as Nilodan (Miracil D) is at present under clinical trial. Promising results have been reported. The drug is given orally in doses of 1 to 2 grammes twice daily for 3 days, the treatment being repeated after a month. Toxic effects include vertigo, epigastric pain, nausea and vomiting, colicky diarrhoea

The usual medical and surgical measures should be employed for complications as they arise, and vesical and rectal polyps which do not resolve with specific therapy may need local treatment

N HAMILTON FAIRLEY

B. DISEASES DUE TO CESTODES

TÆNIASIS—TAPE-WORMS

Definition.—Tæniasis is produced by different forms of tape-worms occurring either as adults in the intestine (intestinal tæniasis) or as the developmental stage in the muscles and other host tissues (somatic tæniasis).

INTESTINAL TÆNIASIS

(1) *Tænia solium* (Linnæus, 1758).—The pork tape-worm measures 2 to 3 metres in length. The head is globular and possesses four suckers, a rostellum and a double row of hooks. The uterus never has more than twelve lateral processes (diagnostic). The ova are spherical, 31 to 40 μ in diameter, having a thick-walled shell and an oncosphere with three pairs of hooklets. The cysticercus stage is passed in the pig (*Cysticercus cellulosæ*), and man becomes infected by eating undercooked "measly" pork. Pickling and smoking do not kill cysticerci.

(2) *Tænia saginata* (Goeze, 1782).—The beef tape-worm measures 3 to 4 metres in length. Its head is cubical with four suckers, but no armature; the uterus contains fifteen or more lateral processes, thus differentiating it from *T. solium*, though its oval eggs, measuring 33 to 40 \times 20 to 30 μ , may be indistinguishable. The cysticercus stage is found in the ox (*Cysticercus bovis*) and man becomes infected by eating undercooked beef.

(3) *Dipylidium caninum* (Linnæus, 1758).—A common tape-worm of the dog is occasionally found in man. Human infestation with *Tænia confusa*, *Tænia africana* and *Bertiella satyri* has been described on two or three occasions.

(4) *Hymenolepis nana*.—This dwarf tape-worm, which is common in Southern Europe, the Southern United States and India, inhabits the small intestine of man. It measures 2.5 to 4.0 cm. in length, has four hemispherical suckers and a short rostellum with a single row of hooks. The eggs measure 30 to 40 μ in diameter and contain an oncosphere. No intermediary host is required, as the eggs hatch out in the intestine. After penetrating the mucosa the embryos develop into cercocysts, return into the lumen of the bowel, become attached by their heads to the villi and develop into mature worms.

(5) *Diphyllobothrium latum* (Linnæus, 1758) (*Tænia lata*, etc.).—The broad, fish tape-worm, some 2 to 10 metres long, possesses an almond-shaped head, but no armature. The immature eggs are oval, operculated and measure 70 \times 45 μ . After 3 to 5 weeks' development in water the hexacanth embryo escapes and is ingested by some species of cyclops or allied crustacean in the body cavity of which it develops into a proceroid larva. Infected crustaceans must be swallowed by certain fish, *i.e.* before the plerocercoid larva develops. Man becomes infected by eating the undercooked, infected fish. Other species, such as *D. cordatum*, *D. parvum* and *D. houghtoni*, have been described on one or two occasions as has also *Diplogonoporus grandis* and *Braunia jassyensis*.

Symptoms.—Symptoms may be absent, or gastro-intestinal disturbance, such as anorexia, voracious appetite, dyspepsia, abdominal pain, colic and diarrhoea may result. Neurasthenia in adults, and headache, convulsions and strabismus are described in children. Occasionally *D. latum* is associated with severe megalocytic anæmia.

Diagnosis.—The diagnosis is made by identifying the appropriate segments or ova in the excreta. Skin hypersensitiveness to tape-worm protein and eosinophilia may be present.

Treatment.—Felix mas and carbon tetrachloride are effective remedies for all the tape-worms, provided preliminary starvation and terminal purgation with salines be instituted. After a liquid diet, consisting of broths, orange juice, dextrose, etc., for 2 days, during which time the bowels are well opened, extractum filicis liquidum in 30 minim doses is given in gelatine capsules or emulsion at 8 0, 8 20, 8 40 and 9 a m. Sodium or magnesium sulphate (gr 240) is administered at 10 a m, and all the motions subsequently passed must be carefully sieved and examined against a black background to identify the head, castor oil must never be used as it dissolves out filicic acid and leads to poisoning. If the head is not recovered, treatment may be repeated in 10 days' time, or 3 months' interval may be allowed, by which time segments will have generally reappeared if the worm has survived. Alternatively, carbon tetrachloride is given in capsules, the maximum adult dose being 3 ml, this is followed by a saline purge 3 hours later. Some report that it is advantageous to combine oil of chenopodium (1 ml) with carbon tetrachloride therapy, as in the treatment of ankylostomiasis. This is important where concomitant infection with ascaris is likely.

In intractable cases a duodenal tube may be passed and specific drugs run directly into the duodenum. If extractum filicis liquidum followed by magnesium sulphate fails to dislodge the head, this treatment may be followed within 48 hours by carbon tetrachloride similarly administered. This treatment, though severe, is generally highly successful.

Mepacrine in high dosage is sometimes effective. It should be given in doses of about 1 g in the course of 1 or 2 hours.

The megalocytic anaemia associated with *D. latum* infestation responds satisfactorily to oral liver extract therapy, but recurs unless the worms be eradicated by specific drug treatment.

SOMATIC TÆNIASIS

(1) *Sparganum mansoni*.—This is the plerocercoid stage of *Diphyllobothrium mansoni* (Cohbold, 1882) which has a somewhat similar life-history to *D. latum*. The adult worm infests the intestine of the dog and cat, the ciliated embryo is ingested by *Cyclops leuckarti* where it develops into a proceroid larva. When swallowed by the second intermediate host, which may be a snake, bird or mammal, including man, the cyclops is digested, the liberated larva penetrates the stomach and, travelling under the peritoneum, reaches the deep somatic muscles, also the iliac fossa, lumbar region, pleura, urethra and eye, where it multiplies asexually by transverse fission, many spargana resulting from a single plerocercoid (Faust). Ingestion of spargana infested tissues by the dog and cat results in intestinal diphyllobothriasis, but the adult stage does not develop in man.

Symptoms.—Pain, swelling and œdema of the subcutaneous tissues and muscles sometimes occur, and in ocular sparganosis, which is common in the Tonkin delta inflammation with pain, redness, œdema, lacrimation and ptosis may result. Human infection in China often follows the direct transference of spargana from infected frogs which are applied locally in the treatment of ulcers, etc. (Joyeux and Houdemer).

Diagnosis.—This is made by finding the unbranched sparganum larvæ embedded by their scolices in a slimy matrix in the tissues.

Treatment.—Where possible the parasite is removed surgically.

(2) *Sparganum proliferum* (Ijima, 1905).—This species affects man in Japan, innumerable spargana producing nodules and honeycombing of the tissues, and elephantiasis if the lymph channels be involved. The adult stage and life cycle are unknown.

(3) *Tania solium*.—The cysticercus stage of *T. solium*, i.e. cysticercosis, is occasionally found in man who may or may not have harboured the adult parasite. The

cyst, which is generally surrounded by a fibrous-tissue capsule, consists of an opalescent bladder containing a single evaginated head with hooklets. Various tissues, including the brain and its ventricles, the liver, lungs, orbit and the somatic muscles, tongue and heart, may be involved. It occurs in Europe, Africa and Madagascar, and in soldiers returning from India and Egypt. Macarthur has found it to be a common source of epilepsy. Man probably acquires the disease by auto infection, or eating uncooked food, such as lettuce, to which dried segments of *T. solium* are adherent.

Symptoms.—Subcutaneous nodules ($\frac{1}{2} \times 2$ cm), muscular weakness, cramp and pains may be encountered, also Jacksonian epilepsy, petit mal, various psychoses and occasionally focal lesions of different types, if the brain be involved (*Cysticercus cellulosa*). The diagnosis is established by biopsy of a subcutaneous cyst, or a radiographic examination revealing calcified nodules in the muscles. Ophthalmoscopic examination may show retinal lesions, while eosinophilia and skin hypersensitiveness and positive complement-fixation reactions with *tænia* antigens may be found. Accessible cysts can be excised, but the prognosis is bad if the brain be involved. The most dangerous period is the sixth to the eighth year, when cerebral disturbances, associated with the death of the cysticerci in the brain, most frequently occur. Mental deterioration and death frequently result, but many of those developing cerebral cysts may recover. Fits should be controlled by phenobarbitone and bromide.

(4) *Tænia multiceps* (Leske, 1780)—*Cænurus cerebralis*, the cystic stage of the canine tape-worm, *T. multiceps*, commonly affects the brain of goats and sheep, it has been recorded in man, producing epilepsy and aphasia.

(5) *Echinococcus granulosus* (Batch, 1786)—This small tape-worm (2.5 to 6 mm in length) inhabits the intestines of dogs, jackals and wolves, it consists of a head with four suckers, a rostellum and hooklets and three or four segments, of which only the terminal one is gravid. In the intermediate hosts, which include sheep, cattle, pigs and man, hydatid disease is produced. Man becomes infested from swallowing water and uncooked vegetables, etc., contaminated with infected canine faeces, or by handling and fondling infected dogs. Hydatid disease is frequently contracted in childhood and is most common in sheep-breeding countries like Australia, New Zealand, the Argentine and South Africa, it also occurs in Iceland but is less frequently encountered in Europe.

After the egg is swallowed, the six hooked embryo escapes from its shell, traverses the intestinal wall, invades the blood-vessels and metastasises generally in the liver, but less frequently in the lungs, brain, bones and muscles, etc., where it loses its hooks and forms a cyst, the wall of which consists of two layers, a laminated outer layer, the ectocyst, and a granular inner layer, the endocyst. As the cyst grows, it exerts mechanical pressure and toxic effects on adjacent host tissue, resulting in inflammatory reaction and the formation of a fibrous tissue capsule known as the adventitia. Endogenous budding from the granular layer of the cyst results in the formation of brood capsules, scolices and daughter and granddaughter cysts. Exogenous budding sometimes occurs, especially in bone, while atypical development in viscera like the liver may result in alveolar or multilocular types of hydatid. It is improbable that a second parasite, *E. multilocularis*, exists.

Symptoms.—The clinical picture is very varied. Cysts may be symptomless for many years until pressure effects are produced, or they may rupture or suppurate with the production of acute illness. Rupture into a vein may lead to sudden death from an embolus of daughter cysts, or to an anaphylactic syndrome characterised by injected conjunctivæ, lacrimation, vasomotor collapse, urticaria, œdema, respiratory distress and eosinophilia. Rupture into the peritoneal cavity may produce an acute abdominal crisis followed by peritoneal echinococcosis, secondary cysts developing from scattered scolices, or if the cyst ruptures into a bronchus natural cure may ensue. Suppuration, especially of liver cysts, is not uncommon, while in some 30 per cent.

of cases their degeneration and death with subsequent calcification lead to natural cure. The inferior aspect of the right half of the liver is the commonest site affected, while the right lung is three times as often involved as the left. Brain cysts closely simulate cerebral tumour, while echinococcosis of bone, owing to its rapid exogenous growth, often leads to a fatal issue, especially when the pelvis and vertebral column are involved, a pressure myelitis may result.

Diagnosis.—A history of contact with dogs in childhood is important, hydatid thrill, if present, is pathognomonic. Collapsed cysts, membrane, scolices and hooklets may be coughed up or passed per rectum, while the aspiration of a clear watery fluid containing considerable amounts of sodium chloride and hydatid elements clinches the diagnosis. Aspiration, however, should never be carried out in lung cysts except on the operating-table owing to the danger of drowning from rupture into the bronchial tract. Radiographic examination is of considerable importance in localising liver and lung cysts, while the complement-fixation and precipitin reactions and the intradermal test have greatly increased the percentage of cases correctly diagnosed before operation. Eosinophilia may occur, especially if a cyst has recently ruptured.

Treatment.—No medical treatment is available except for the anaphylactic syndrome, when adrenaline (10 minims of 1 in 1000 solution) should be administered. As a rule, calcified cysts should not be operated on. After the injection of formalin to kill scolices in hepatic cysts the contents should be evacuated and the adventitia sewn up in smaller-sized cysts, suppurating and large cysts must be drained. Special care must be taken to prevent soiling of the peritoneum with the cyst contents in hepatic hydatid, as secondary peritoneal echinococcosis is liable to develop.

N HAMILTON FAIRLEY

C. DISEASES DUE TO NEMATODES (ROUND-WORMS)

STRONGYLOIDIASIS

Strongyloides stercoralis (Bavay, 1876)—A common tropical parasite of man, the female worms living in the jejunum and duodenum, and in massive infections invading the bile and pancreatic ducts, the stomach and colon.

Ætiology.—The eggs hatch out rhabditiform larvæ which appear in the fæces rarely, where intense diarrhoea is present, the eggs (50 to 80×30 to 34μ), which resemble ankylostome ova, may be found. The rhabditiform larvæ give rise either directly, or indirectly through a sexual circle, to filariform larvæ which invade the skin or mucosa and follow a similar route to ankylostomes proceeding via the lung to the intestine.

Pathology.—Intestinal catarrh or an enteritis, with extensive erosions of the mucosa, giving rise to a "beefsteak" appearance, may occur in heavy infections.

Symptoms.—Initial dermatitis and lung symptoms may be seen during the first few days. Mild infections show no symptoms, severer infections may present epigastric discomfort after meals, flatulence and diarrhoea which occasionally is very intractable. Occult blood may occur, urticaria and œdema sometimes develop at the site of entry of infective larvæ and dermal sensitivity can be demonstrated to strongyloid extracts (Fulleborn).

Diagnosis.—This is made by finding the rhabditiform larvæ in the stools, which should be mixed with water and strained through muslin. Hook worm embryos have a longer pre-œsophageal mouth cavity and occur within the egg.

Treatment.—Gentian violet, introduced as a specific by De Langar, is given as a keratin-coated pill (gr. 1) thrice daily before food until a course of gr. 50 has been taken. In intractable cases, 25 ml. of a 1 per cent. aqueous solution can be administered through a duodenal tube. For the intravenous route 25 ml. of an 0.5 per cent. solution is recommended on alternate days for 10 days. Though favourably reported on, gentian violet treatment by no means always cures.

Allied helminths, including *Rhabditis pellio* (Schneider, 1886) and *Turbatrix aceti* (Muller, 1783), the common vinegar worm, have been reported in the vaginal exudate and urine of women.

FILARIASIS

An invasion of man by members of the family *Filariidae*. Several species are known to infest man, *Filaria bancrofti* or *Wuchereria bancrofti*, *F. malayi* or *W. malayi*, *F. loa* or *Loa loa*, *F. perstans* or *Acanthocheilonema perstans* transmitted by *Culicoides austeni*, *F. ozzardi* or *Mansonella ozzardi*, the insect vector being *C. furens* and *Dipetalonema streptocerca* (Macfie and Corson, 1922) found commonly in the skin of natives on the Gold Coast and parts of Belgian Congo. Only the first three are of clinical importance.

(1) *F. bancrofti* (Cobbold, 1877).—This parasite has a widespread tropical distribution, being especially common in India, the West Indies, Porto Rico, Southern China and the Pacific Islands. The adults are like fine catgut (♂ 30 to 40 mm. long; ♀ 76 to 100 mm. × 0.2 mm.); they inhabit the lymphatics and periglandular lymphatic tissue, and produce embryos which subsequently invade the blood-stream, living in the lungs and thoracic blood-vessels by day and appearing in the peripheral blood only at night—nocturnal periodicity. The embryos are enclosed in a loose sheath and measure 230 to 320 × 7.5 to 10 μ . As Manson first showed, the intermediate host is a mosquito (chiefly *Culex fatigans*), which sucks the embryos out of the blood at night; metamorphosis subsequently takes place in the thoracic muscles. The mature embryos are inoculated into man via the proboscis (Low). Development in the insect vector takes from 10 to 40 days, depending on the temperature, etc. In the Pacific two filaria zones are encountered. Filariasis in New Guinea and New Britain is of the usual nocturnal type and transmission is chiefly by *C. fatigans*. In islands east of 170° east longitude filaria is transmitted mainly by the day-biting mosquito, *Aedes scutellaris pseudoscutellaris*, and is non-periodic in type. This holds in the Samoan, Wallis, Friendly, Fijian, Ellice, Gilbert and Society island groups. Though there are no morphological differences between the adults and microfilariae of the nocturnal and non-periodic types of *F. bancrofti*, it is still possible they may represent different strains or subspecies.

Pathology.—The parent worms often produce little obvious damage, the infection then being recognised only by the presence of microfilariae in the blood. Pathological changes, associated with the presence of filaria worms, however, may be found in the tissues of such patients (O'Connor and Hulse), notwithstanding the absence of symptoms, while in others, especially when hyperinfection has extended over many years, the most gross and grotesque pathological manifestations may be found. The various changes in the lymphatics and lymph glands are partly of mechanical origin and partly attributable to the effects of helminthic toxins which induce lymphangitis with resulting lymph stasis and lymph oedema. Lymph oedema and inflammatory tissue reaction ensure an increased protein content of the tissue fluids; this stimulates growth and results in hyperplasia of the skin and subcutaneous tissues, ultimately leading to elephantiasis. Recurring lymphangitis and blocking of the lymphatics may result in death of adult worms, but even if this does not happen, obstruction of the lumina of the lymphatics proximal to the worms will prevent the escape of

microfilariae into the circulation. These are the probable reasons why microfilariae are no longer demonstrable in the blood of patients with elephantiasis.

Symptoms—The incubation period is variable. Some 6 months to 2 years may elapse before early clinical features such as urticarial swellings, filarial nodules and thickened lymph cords, lymphangitis, adenitis, epididymo orchitis, or lymph scrotum appear. Eosinophilia and skin hypersensitivity to *Dirofilaria immitis* antigen are generally present at this time, but no microfilariae are demonstrable in the blood. Excision of a nodule and subsequent microscopic examination may reveal adult worms. As in loa loa infestation, it may be 2 years before embryos are demonstrable, even when considerable quantities of blood are examined.

Lymphangitis is associated with rigors, high temperature, tender enlargement of the lymphatic glands, red lines in the course of the lymphatics and inflammatory swelling of the affected tissues. The "elephantoid" fever usually lasts 1 to 3 days, if the temperature persists longer superadded streptococcal infection should be suspected. The filarial nodules described by O'Connor originate as a local tissue reaction around dead filarial worms located in the lymphatics, from here red lines caused by inflamed lymphatic vessels may radiate down the limb. The lymphangitis is well defined and the skin and subcutaneous tissue are dull red, tense and oedematous.

Enlarged groin glands are common and if associated with a mass of varicose lymphatics (lymphatic varix) may be mistaken for a hernia. Microfilariae are often found in the aspirated lymph. If lymphangitis ensues there is much local inflammatory swelling, tenderness and pain. The axillary, epitrochlear and cervical glands occasionally become enlarged, especially in non-periodic filaria, while enlargement of the deep-seated glands—iliac, lumbar, mesenteric, retroperitoneal and thoracic—sometimes occurs. Living or calcified worms may be found in such glands, and secondary coccal infection is said sometimes to lead to fatal septicæmia. Involvement of the retroperitoneal lymphatics may cause abdominal pain, associated with tenderness and rigidity of the abdominal muscles, vomiting, hicough and fever, death from streptococcal peritonitis may follow. Endemic funiculitis or lymphangitis of the spermatic cord is often associated with lymphangectasis, and is characterised by acute tenderness and local inflammation of the scrotum and cord. Filarial epididymo-orchitis is also not uncommon. It produces fever, shivering and pain in the testicle which rapidly enlarges and is associated with exudation of fluid into the tunica vaginalis. The swelling subsides in a few days, but permanent thickening and a filarial hydrocele or chylocele may result. Recurrences are common. Lymph scrotum is due to an inflammation of the scrotal lymphatics, which may become dilated and tortuous and form small vesicles exuding lymph containing microfilariae. Recurrent attacks lead to elephantiasis. Chyluria results from obstruction and dilatation of the thoracic duct itself or of some of the chyle carrying intestinal lymph vessels. Subsequent rupture of dilated lymphatics into the pelvis of the kidney, ureters or bladder leads to chyluria, or, if chyle escapes into the peritoneal cavity, to chylous ascites.

Elephantiasis results in people repeatedly exposed over long periods of time. The lower limbs are most frequently involved, next the scrotum and next the arms. Elephantiasis of the mammae, vulva and penis are rare. The condition is generally preceded by recurrent attacks of lymphangitis with fever and secondary dermatitis and cellulitis. Occasionally such a history is lacking. Different clinical types are described varying from slight uniform enlargement of the limbs with perceptible thickening of the skin, to gross enlargement with characteristic elephantoid appearance and deformity. The skin becomes coarse and thickened, later, indolent ulceration or abscesses may form, or a coarse warty appearance develops (Elephantiasis verrucosa). Finally the skin becomes leathery in consistency and thrown into rugæ, while the hypertrophy of the subcutaneous tissues become so great that the patient is practically immobilised by mere increase in the weight of the lower limbs or scrotum.

Patients inflicted with this condition may live for many years, finally dying from intercurrent disease.

Diagnosis.—Prior to the appearance of embryos in the blood, eosinophilia associated with a positive intradermal skin test will suggest the diagnosis. If nodules are present, biopsy should be performed and examination made for the presence of adult filaria in tissue section. When searching for embryos, blood should be collected at the appropriate time (about 10 p.m. to 12 midnight in the nocturnal type and as much as 2 ml. of blood examined in thick films. The fact that the lymphangitis often originates in a nodule in the course of the lymphatic vessels and is of retro-grade not the ordinary ascending type, should suggest a filarial origin.

Filarial elephantiasis should be distinguished from the familial type of elephantiasis known as Milroy's disease, and from elephantiasis secondary to recurrent streptococcal lymphangitis, or blockage associated with tuberculosis or carcinoma of the lymph glands or surgical excision.

Treatment.—Prophylaxis depends on mosquito destruction and the use of mosquito nets, etc. Certain trivalent and pentavalent organic antimony compounds have been favourably reported on in animal filariasis. Fouadin kills the microfilariae in dogs infected with *Dirofilaria immitis* but not the adult worms, and Neostam (stibamine glucoside) has recently been reported as curing filariasis (*Litomosoides carinii*) in the cotton rat by destroying the adult parasites. Favourable results have recently been reported in human filariasis (*F. bancrofti*) following intensive treatment with Neostibosan, 12 to 15 g. being given in 14 days (Culbertson). The drug acts on the adult worms not on microfilariae, which may take many months to disappear. The blood became entirely negative in two-thirds of the patients after 13 months. Unfortunately, severe toxic reactions developed in some instances and for this reason the treatment appears hardly justified.

Much more promising results have followed the use of the piprazines in the treatment of *F. bancrofti*. The drug of choice is Hetrazan (1-diethyl-carbamyl-4-methylpiperazine hydrochloride) which is given orally in a dosage of 2 mg. per kg thrice daily for 11 to 22 days. Hetrazan has a pronounced effect on circulating microfilariae, patients showing a negative or markedly reduced counts as early as the second day of treatment. Patients followed up to 5 months have shown no recurrence and the available evidence suggests it also exerts a lethal action on the adult worms.

If secondary streptococcal infection has supervened, sulphonamide therapy or penicillin is indicated. Surgical intervention may be necessary for septic complications, such as filaria abscess and various elephantoid conditions. In elephantiasis of the legs elastic bandaging, massage and rest, with elevation of the limbs, are desirable. Elastic stockings should be washable, porous and made to fit, extending from the dorsum of the foot to above the knee.

(2) *Filaria malayi*.—The adult parasite resembles *W. bancrofti* but it is not as widespread. It occurs in India, Dutch East Indies, the Malay Peninsula, China and Indo-China. The microfilariae have a nocturnal periodicity and the insect vectors are certain species of *Mansonioides* and *Anopheles*. The microfilariae were first described by Brug (1929) but the adult worms were not discovered until 1940 by Rao and Mapleston who removed them from a cyst in the forearm of an Indian. The clinical aspects of this infection have not been closely studied. Elephantiasis, most commonly of the lower limbs, is associated with the infection. Treatment is the same as that for bancroftian filariasis.

(3) *Loa loa* (Cobbold, 1864).—Human infestations with this parasite occur in West Africa. The adults inhabit the subcutaneous and retroperitoneal tissues, while the sheathed embryos have a diurnal periodicity (9 a.m. to 9 p.m.); several years may elapse before embryos appear in the peripheral blood. Transmission is by certain species of mango-fly (*Chrysops dimidiata* and *C. silacea*) which feed in the daytime. Clinically the worms give rise to urticarial eruptions and puffy, painless, white swell-

ings the size of a hen's egg, lasting 2 to 3 days, known as Calabar swellings. These are due to an œdema of the subcutaneous tissue and probably represent an anaphylactoid reaction to helminthic products or toxins. Leucocytosis associated with a marked eosinophilia (20 to 60 per cent) is characteristic, and dermal hypersensitiveness to dirofilarial extract is shown in almost every case. Positive complement-fixation reactions are also given with dirofilarial alcoholic extracts. Neuritic pains may also be complained of. Not infrequently the worms appear about the eye, and in their migration across the conjunctivæ give rise to transient conjunctivitis and lacrimation. Where visible, the worm should be surgically removed under local anæsthesia.

Treatment with Hetrazan is often effective. Because of the frequent severe reactions to treatment the drug should be given first in small doses and the dose increased in the first 3 or 4 days up to 2 mg per kg, 3 times a day. Continue treatment for up to 21 days. The immediate reactions include urticaria, local irritation in regions where the worm is present, effusions into joints and irregular or generalised œdema.

ONCHOCERCIASIS

Onchocerca volvulus (Leuckart, 1893)—This nematode, first found on the west coast of Africa, inhabits the subcutaneous or connective tissues of man, often giving rise to nodular, subcutaneous, cystic tumours, 1 to 10 cm in diameter, over which the skin is generally movable, and in which lie entangled masses of worms and embryos encased in dense fibrous tissue. The swellings are particularly common around the elbows, knees, ribs, iliac crests and greater trochanters. Unsheathed microfilariae may occasionally be demonstrated in the skin, especially of the loin and thigh, as well as in the circulatory blood and subcutaneous lymph channels, even though no evidence of disease exists. Dermal lesions, including achromia, xeroderma and pseudo ichtyosis, are attributed to embryos located in the skin (Laird). Pruritus may be intense, especially at night. *Onchocerca* tumours of the head are not infrequently associated with ocular complications. Blindness may result from retinochoroiditis or punctate iritis when embryos are found in the anterior chamber. Blacklock has shown that transmission is by the buffalo gnat, *Simulium damnosum*. In East Africa it is also transmitted by *S. neavei*. Localised tumours may be removed under local anæsthesia.

The parasite called *Onchocerca cutcutiens* (Brumpt, 1919) is found in Guatemala and Mexico. Its status as a distinct species has for some time been doubtful, and the recent work of Strong indicates it is the South American form of *O. volvulus*. It produces flat nodes (Guatemala nodules) up to 2 cm in diameter, especially affecting the scalp and face, and an eruption known as "coastal erysipelas", associated with pain, tumefaction and fever, may result from secondary streptococcal infection of the skin due to scratching, the irritability being caused by microfilariae in the corium. More important are the ocular lesions caused by microfilariae, piercing the capsule of the nodules and invading the tissues of the eye, producing conjunctivitis, punctate iritis, keratitis and choroiditis. Blindness commonly follows (Strong). An eosinophilic leucocytosis is the rule. Diagnosis is made by demonstrating the microfilariae in the milky fluid aspirated from the nodules, or in adjacent pieces of skin shaved off and teased up in saline at 37° C for microscopical examination. Transmission is by three different species of *Simulium*, the coffee flies living at a height of 2500 to 5000 feet. The nodules should be excised whenever possible, especially those in the vicinity of the eyes. Some improvement in the ocular condition may follow this procedure.

Two drugs, i.e., suramin and Hetrazan, are at present employed with some success. Suramin gives somewhat the better results.

Suramin (Antrypol, Germanin)—For adults, 10 g intravenously once every 5

days for 5 to 15 doses. Children in proportion. An initial dose of 0.2 g. is sometimes given to test for idiosyncrasy to the drug, which shows itself as proteinuria and oliguria with casts, appearing within 24 hours of dosage. Individuals reacting in this way should be given Hetrazan as an alternative. Toxic reactions related to the worm infestation also appear after 2 or 3 doses of suramin. They are similar to those described below, but usually less severe.

Hetrazan.—For adults, 2 mg. per kg. orally once on the first day, twice daily on the second day, thrice daily on the third and consecutive days up to the twenty-first day. Side-effects appear early after the first few doses and include burning of the eyes, congestion of conjunctival vessels, hard *œdema* of the face and ears and sometimes of the limbs. Skin lesions may become *œdematous* and pruritus is often severe. Antihistamine drugs relieve the reactions.

TRICHINIASIS

Definition—A disease produced by the embryos of *Trichinella spiralis* (Owen, 1835) during their migration from the human intestine to the muscles

Ætiology—Infection is acquired by eating raw or underdone pork in which the larvæ have encysted. After the cyst walls have been dissolved by the gastric juice the embryos mature and breed in the small intestine. The gravid female bores into the mucosa, depositing hundreds of viviparous larvæ ($100 \times 6\mu$) which reach the muscles from about the ninth to the fortieth day via the liver, lung and left heart. The adults are small (σ 1.4 to 1.6 mm \times 0.04 mm, ϕ 3 to 4 mm \times 0.6 mm) and live only a few weeks, whereas encysted larvæ may survive for 25 years, though they often calcify within 6 months. Rats act as reservoir hosts.

Symptoms—For the first week during the invasion period gastro intestinal symptoms develop with nausea, vomiting, colic and diarrhoea with perhaps blood and mucus, then when migration of larvæ commences myositis of the tongue, laryngeal and intercostal muscles and the diaphragm occurs, giving rise to difficulty of swallowing, speech and respiration. The muscles of the jaws, arms, legs and abdomen may also be involved with stiffness and pain, the affected areas are exquisitely tender and hard to the touch. Oedema, especially of the face, urticaria, leucocytosis with high eosinophilia, prolonged remittent fever (102° to 104° F) and sweating are characteristic. Pulmonary features are common, and occasionally hæmoptysis occurs. Cachexia develops and, finally, during the period of larval encystment, the patient may succumb from toxæmia with respiratory disturbance and coma.

Diagnosis—Early, the disease may be mistaken for ptomaine poisoning, enteritis or dysentery, and later for rheumatic fever or typhoid. The intense eosinophilia should arouse suspicion while later biopsy of a piece of the affected muscle such as the deltoid at its tendinous insertion will often reveal precystic or encysted larvæ. Embryos may be found in the blood, especially from the twelfth to the twentieth day, by taking it with 10 volumes of 3 per cent acetic acid and centrifuging the deposit. Intradermal and precipitin tests are often positive to an antigen manufactured from the embryos (Bachman). At a later stage, calcified cysts may sometimes be visualised by radiography.

Prognosis—This largely depends on the intensity of the infection, the mortality rate varying in different outbreaks from 1 to 30 per cent. Convalescence is often slow and muscular atrophy may follow.

Treatment—**PROPHYLACTIC**—This depends on careful meat inspection, and lequite boiling of pork, curing by smoking and salting is ineffective. Special care should be taken at necropsy to prevent infection.

CURATIVE—No specific treatment is known, but every effort should be made to expel the adult worms. Purgatives and glycerin, santonin, thymol and turpentine are employed for this purpose.

ÆSOPHAGOSTOMIASIS

(1) *Æsophagostomum apistomum* (Willach, 1891)—This nematode frequently affects certain anthropoid apes and monkeys in West Africa, and not uncommonly man in Northern Nigeria. The rhabditiform larvæ exsheathe in the cæcum, invade the bowel wall and give rise to inflammatory nodules in which they develop, later they erupt into the intestine and mature. Dysentery like symptoms, with hæmorrhage and occasionally peritonitis and septicæmia, may result. The ova are indistinguishable from ankylostome eggs, but fortunately thymol, oil of chenopodium and carbon tetrachloride are specific for the adults (Faust).

(2) *Æsophagostomum stephanostomum* (Raillet and Henry, 1909).—The adult worms present minor differences, and in the only human case recorded, by Thomas in Manaus, Brazil, nodules were found in the ileum as well as in the colon.

ANKYLOSTOMIASIS

Synonyms.—Uncinariasis; Hookworm Disease.

Definition.—Ankylostomiasis is caused by members of the family *Ankylostomidae*. Five species may affect man—*Ankylostoma duodenale* (Dubini, 1843), *Necator americanus* (Stiles, 1902), *A. malayanum* (Alessandrini, 1905), *A. braziliense* (Gomez de Faria, 1910) and the *A. caninum* (Ercolani, 1859). The first two species commonly affect man, the third and fourth rarely, while the larvæ of the fifth may cause creeping eruption.

Ætiology.—*A. duodenale*.—Adults ♂ 8 to 10 mm. \times 0.4 to 0.5 mm.; ♀ 12 to 18 mm. \times 1 mm. Ova are elliptical, thin-shelled containing vitellus, segmented into 2 to 8 spherules, and measure 55 to 65 \times 32 to 45 μ . *N. americanus*.—Adults ♂ 7 to 9 mm. \times 0.3 mm.; ♀ 9 to 12 mm. \times 0.4 mm. The ova measure 64 to 75 \times 36 to 40 μ . The buccal armature of the two species differs. The capsule is smaller in *N. americanus*, and has an irregular border instead of the four ventral hook-like teeth of *A. duodenale*; there is also a pair of semilunar plates. All subsequent description applies to both these parasites.

When fæces containing ova are deposited on moist earth the rhabditiform larvæ hatch out in 24 to 48 hours: later they moult twice, developing into filariform larvæ which may remain viable for 3 to 4 months. On contact with human skin the latter bore their way into the blood-vessels, pass to the right heart and lungs whence they progress via the trachea, œsophagus and stomach to their natural habitat in the duodenum and small intestine; here they mature and breed, egg-laying commencing in about 5 weeks. The worms attach themselves firmly to the mucosa, feeding on blood and may cause local bleeding (especially *A. duodenale*), though the stools generally give a negative test for occult blood. At necropsy œdema of the legs and sacrum is common, and effusions and petechiæ may involve the serous sacs. The heart is dilated and shows marked fatty degeneration, as do also the liver and kidneys. The duodenum and jejunum may present petechial hæmorrhages, especially at points where the worms are attached.

Symptoms.—At onset the larvæ may produce ankylostome dermatitis or ground itch, which clears up within 2 weeks unless secondary infection has occurred. In heavy infection symptoms may appear within 1 to 2 months. These are largely related to the anæmia which is microcytic and hypochromic in type; there is a low colour index, and an increased blood volume. The counts in a severe case would show erythrocytes = 1,000,000 to 2,500,000 per c.mm.; hæmoglobin = 10 to 25 per cent.; colour index = 0.5. Leucocytes are normal or slightly increased in number, and eosinophilia is characteristic. Mild cases may be symptomless, and it is uncommon for the well-fed European to develop anæmia unless hyperinfection be present. Anæmia generally occurs in patients living on a borderline diet, poor in animal protein and iron-containing foods. Those moderately infected may complain of mental and physical lethargy, hyperacidity, epigastric tenderness, palpitations and shortness of breath. The really severe case may show a tallow-yellow discoloration of the alæ nasi and forehead, a dry, earthy-coloured skin, pallor of the mucous membranes, mental sluggishness, dilated stomach and epigastric tenderness; earth-eating sometimes occurs and constipation is frequent. Dyspnoea, cough, palpitations, pulsating cervical veins and hæmic murmurs are common; retinal hæmorrhage, œdema of the feet and serous effusions may occur. Hook-worm disease causes great economic loss to the community by lowering the individual's physical and mental

capacity for work and predisposing to secondary infections like pneumonia and dysentery. In Europe outbreaks have sometimes occurred in miners.

Diagnosis—A microcytic, hypochromic anæmia, especially if associated with eosinophilia, should arouse suspicion in a tropical patient, and the stools should be immediately examined for ova, preferably by the Clayton Lane flotation method.

Prognosis—The mortality rate is low, even in natives, the chief danger being anæmia, which predisposes to intercurrent disease unless specific treatment be instituted. Hook-worm infection is especially serious in children owing to its effects on their mental and physical development. In the well fed European the disease rarely produces serious manifestations.

Treatment—**PROPHYLACTIC**—This includes the treatment of carriers, the substitution of latrines for promiscuous defæcation, the proper disposal of night soil, the treatment of contaminated ground and the wearing of good shoes and boots. Sanitation in mines must be satisfactory.

CURATIVE.—There are three specific drugs which are widely used in the treatment of ankylostomiasis: (1) tetrachlorethylene, (2) carbon tetrachloride and (3) oil of chenopodium. Either tetrachlorethylene or carbon tetrachloride can with advantage be combined with oil of chenopodium, and this should be done whenever possible. After saline purgation, the object of which is to get rid of both drug and parasites, the stools should be examined and the number of worms recorded if time permits. In 7 to 10 days' time the stools are re-examined, if ova have reappeared another course of treatment may be considered advisable.

(1) *Tetrachlorethylene*—Adult dosage 2 to 3 ml. This drug is effective against *A. duodenale*, *N. americanus* and *Enterobius vermicularis*. It is the safest and cheapest anthelmintic, and is given in a single dose, either in gelatine capsule or shaken up with $\frac{1}{2}$ to 1 oz of magnesium sulphate in water, 1 ml of oil of chenopodium should be added or administered in a gelatine capsule. These are given in the early morning on an empty stomach. No food is permitted until the bowels have acted, and magnesium sulphate (4 drachms) should be repeated after 3 hours if necessary.

(2) *Carbon tetrachloride*—Adult dosage 2 to 3 ml. This drug is of value in thread worm and ascariis infestation, as well as in ankylostomiasis. The drug is given in a dosage of 3 ml, either in gelatine capsules or in milk or in magnesium sulphate solution. It is administered in the early morning on an empty stomach, and food is withheld until the bowels have been well opened—if necessary with magnesium sulphate. If available it is advantageous to combine this treatment with oil of chenopodium. As a routine, 1.5 ml of carbon tetrachloride and 0.5 ml of oil of chenopodium are administered in a mixture containing $\frac{1}{2}$ oz of magnesium sulphate, and the same dose is repeated in 1 hour's time. If necessary, a saline purge is given 3 hours later. Carbon tetrachloride when administered in poisonous doses causes a central lobular necrosis of the liver, with fatty degeneration. Clinical evidence of poisoning include vomiting, hepatic pain and tenderness, jaundice, hæmaturia, and temporary anuria. Fatalities have been reported, and it is inadvisable to employ this drug to (1) alcoholics, or (2) patients suffering from calcium deficiency, cirrhosis of the liver, or renal disease. A preliminary course of high protein dietary might lessen the tendency to or prevent hepatic necrosis developing in such cases.

(3) *Oil of chenopodium*—Adult dose 1 to 2 ml. This drug is effective against ascariis as well as ankylostomiasis. Its therapeutic action is dependent on the ascaridol content, which is by no means always constant. It is best given in gelatine capsules or it may be taken in an emulsion or in water mixed with other anthelmintics such as tetrachlorethylene or carbon tetrachloride. If used alone, the drug may be administered in divided doses, i.e., $\frac{1}{2}$ ml half hourly for 2 hours, or in a single dose of 2 ml followed by a saline purge. Narcosis and other ill effects have followed its

administration, and cumulative effects have been noted. Treatment should not be repeated under 10 days. In case of poisoning, digitalis and epinephrine have been found useful, but there is no chemical antidote.

The effectiveness of treatment is determined by the disappearance of symptoms, and of ova from the faeces as revealed by later microscopic examinations.

Treatment of anaemia depends on (1) eradication of the ankylostome infection, (2) a well balanced diet containing meat, proteins, fruit, vegetable, lipoids and vitamins, and as regards the latter a whole-wheat bread is most desirable if obtainable. (3) iron in large dosage, (4) treatment of intercurrent infections, such as malaria.

Ground itch may be treated with an ointment containing zinc oxide and salicylic acid. If there is secondary coecal infection, antiseptic dressings are indicated.

ASCARIASIS

Definition.—An intestinal infection of man with the round worm *Ascaris lumbricoides* (Linnaeus, 1758).

Ætiology.—Adults ♂ 17 to 25 cm × 3 mm, ♀ 20 to 40 cm × 5 mm. The eggs are yellow, elliptical, possess a thick outer shell and measure 50 to 70 × 40 to 50 μ. Ova passed in human faeces develop in night soil, and the fertilised eggs, swallowed by man in contaminated water or food, pass into the intestines where the larvae penetrate the bowel wall and migrate to the lungs, sometimes producing ascari pneumonia, thence, via the trachea and œsophagus, they reach the intestine (Stewart). Ova appear in the faeces in 2 to 2½ months.

Symptoms.—During larval migration urticaria, ascari pneumonia and, more rarely, ascari nephritis may occur. Pulmonary complications appear early in the first week and are generally transient in nature. Adult worms may produce symptoms by toxic, reflex or mechanical means. Sensitised individuals occasionally develop rashes such as urticaria and œdema of the face, and in children, gnashing of the teeth, enuresis and convulsions may occur (ascari dysentery), while masses of coiled up worms sometimes produce acute intestinal obstruction. Perforation of the intestine leads to peritonitis or localised abscess from which worms may be discharged. Wandering worms may produce appendicitis or obstruct the pancreatic or bile ducts causing jaundice, or reach the liver producing liver abscess or cholecystitis. They have been known to enter the larynx and cause œdema of the glottis or even to appear in the antrum of Highmore.

Treatment.—Oil of chenopodium (15 ml), carbon tetrachloride and tetrachlorethylene (3 ml) are specific remedies, in combination given as in ankylostomiasis they are particularly efficacious (see Ankylostomiasis). Santonin (gr 3 to 5) is the stock remedy, it may be given on consecutive or alternate days on three occasions combined with preliminary starvation and followed by castor oil, in children, where the dosage is proportionately lowered, it may be combined with scammony or castor oil. Hexylresorcinol in 1 g doses is also recommended and should be followed by a saline purgative. Worms sometimes take 48 hours to be ejected, and the only index to cure is the permanent disappearance of ova.

liberated and attach themselves to the mucosa. Occasionally they invade the appendix, colon and terminal ileum.

Symptoms—Clinical features are generally entirely absent, but reflex symptoms are described in children and occasionally urticaria and eosinophilia are induced. Rarely verminous appendicitis and peritonitis may result, and possibly caecal lesions may open up the way for other infections.

Treatment—Thymol and oil of chenopodium may be effective, but worms are often difficult to eradicate.

ENTEROBIASIS

Definition—Infection by the thread or pin worm *Enterobius vermicularis* (Linnaeus, 1758), formerly known as *Oxyuris vermicularis*. Adults ♂ 3 to 5 mm, ♀ 10 mm \times 0.6 mm. The ova measure $50 \times 20 \mu$, and are thin shelled, colourless, plano-convex and contain coiled embryos; they are rarely found in the faeces, being mainly liberated in the perianal region from migrating gravid female worms at night, after the patient has gone to bed. The maximum length of the life cycle is 30 days, long-standing enterobiasis resulting from autoinfection via the infected fingers of the patient.

Symptoms—The worms inhabit the colon, and when the patient is warm in bed at night may produce great discomfort and itching by migrating out through the anus. Eczema and pruritus ani may result causing sleeplessness and neurasthenia. Sexual disorders, vesical irritability, frequent micturition, prolapsus ani and mucoid secretion may be observed, also in young girls vaginal discharge. Catarrhal appendicitis sometimes occurs, and worms may wander into the stomach.

Diagnosis—Eggs are best demonstrated by swabs made from the perianal skin or by a moistened camel's hair brush applied to the anal folds and perianal skin. Less than 1 per cent of proved cases have demonstrable ova in the faeces. Inspection of the anal region at night immediately when itching commences may reveal the gravid female worms outside the anal canal before they have had time to retreat to the rectum.

Treatment—The basis of successful treatment is the prevention of auto-infection. This is best done by the most scrupulous care of the hands and nails which may become contaminated (1) by scratching in the anal region, especially during sleep, (2) when completing the anal toilet with sanitary paper or (3) from infected clothes. The nails should be kept short, and the hands well washed and scrubbed with carbolic soap immediately on waking, after defaecation and every time there has been possible contact with infected material or clothing. Bathing drawers or pyjamas should be worn at night and sterilised each day, and infected children should occupy separate beds. Enemas of 4 to 8 fl oz of hypertonic saline solution should be injected immediately the anal irritation commences for at this time the worms are accessible and can be washed out from the rectum (Macarthur). After local bowel treatment each night yellow mercuric oxide ointment should be applied to the perianal region. The process should be repeated each night whenever anal irritability recurs. If re-infection be prevented this measure alone will generally result in cure.

Gentian violet appears to exert a specific lethal effect on the adult worms. Wright advocates special keratin coated tablets of this drug the adult dose being gr 1 thrice daily before meals for 8 days, this course is repeated after a clear interval of 7 days. Toxic features include anorexia, nausea, abdominal cramp and vomiting.

The disease often involves several members of the same family or several people living in the same house. It is advisable that they should be treated simultaneously to prevent reinfection.

D. DISEASES DUE TO INJURIOUS ARTHROPODS

TICK BITES

Apart from relapsing fever, tularæmia, Russian spring-summer encephalitis and certain typhus-like fevers the bites of several species of ticks, including *Dermacentor andersoni*, *D. venustus*, *Hæmophysalis punctata*, *Ixodes ricinus* and *I. holocyclus*, may give rise to paralysis in man. Cases have been recorded from Australia, South Africa and the United States. The incubation period varies from several hours to 6 days; the bites, which are generally situated on the nape of the neck, are painful and edematous, and the disease, which is afebrile, may be fatal, especially in children. The paralysis is of lower motor neurone type resembling that seen in infantile paralysis, and develops first in the legs and later in the arms and neck. In removing ticks the parasite should not be forcibly extracted until paraffin or carbolised oil has been applied, as this causes withdrawal of the head and so prevents it being broken.

MITES

Apart from scabies, camel itch and copra itch, all of which are caused by different species of mites, the scrub-typhus group of fevers are transmitted by larval mites. The harvest mites of temperate climate cause considerable itching and skin erythema, which comes on 12 hours after exposure and increases for 36 hours, sometimes persisting for several days. Mite bites may be prevented by anti-mite fluids, such as dibutyl or dimethyl phthalate applied to the socks and clothing; they are treated by washing the legs with benzine, green soap or salt solution, while the itchiness may be combated, as in flea-bite, by the use of 1 in 10 carbolic lotion or an ointment composed of acid. carbol. (gr. 10), menthol (gr. 5), zinc oxide (gr. 60) and adip. præp. (1 oz) (Roxburgh) may be used. Larval mites of the family *Trombididae* are known to cause skin eruptions in various parts of the tropics. One, in the West Indies, produces red mite dermatitis (bête rouge), the little crimson spot in the middle of the itchy papule being diagnostic: another, in Mexico, has a predilection for the skin of the eyelids, prepuce and axilla. Owing to the fact that many adult mites have never been identified, species names are not generally available for the larvæ. Scrub-itch commonly results from the bites of trombiculid larval mites, such as *T. minor* in Australia and New Guinea (*vide* Tsutsugamushi Disease, p. 288).

TONGUE WORMS

The adults, which are degenerated, segmented arachnids superficially resembling tape-worms, live in the lungs or nostrils of certain carnivora or ophidia, and deposit their eggs on vegetation; when these are eaten the larvæ encyst in the viscera of the intermediate host. Several species have been reported in man, including *Langatula serrata*, which occurs in parts of Europe and Brazil, the larvæ encysting harmlessly in the human liver, and *Porocephalus armillatus*, which encysts in the mesentery, liver and lungs. This infection is not uncommon in the Belgian Congo. Pulmonary symptoms have been reported, and sometimes the larval forms wander free in the

peritoneal cavity. If the cysts have become calcified they may be detected by radiographic examination; otherwise the disease is only recognised at necropsy. No treatment is known for either linguatulosus or porocephaliasis.

INSECT BITES

Apart from specific disease transmission, bites from mosquitoes, biting flies, midges, lice, fleas, bugs, bees, ants, wasps and hornets may cause considerable inconvenience to man and occasionally result in local sepsis or septicaemia which may end fatally. Mosquito bites occasionally give rise to streptococcal septicaemia, and those of horse-flies to anthrax.

Locally, insect venom may have hæmolytic, neurotoxic or irritant effects producing limited inflammation or dermal whealing of anaphylactoid origin dependent on previous sensitisation, as Boycott has proved for midge bites. The stings of bees, wasps and hornets are invariably painful, and in certain situations like the tongue and fauces may lead to respiratory obstruction, or in the larynx to death from œdema of the glottis. Anaphylaxis may follow bee or wasp stings in a sensitised individual. Such patients have been known to develop profound vasomotor collapse, become comatose and die in 20 minutes. In a case of wasp sting seen by the writer, the patient, who gave a history of having been stung on the scalp 6 years previously, was again stung on the third right finger; a wheal about 2 cm. in diameter rapidly appeared with surrounding erythema, and within 5 minutes the patient developed headache, lacrimation and injection of the conjunctivæ. Giddiness, nausea, severe vomiting, rapid low tension pulse with vasomotor collapse, generalised urticaria, especially involving the arms and neck, and respiratory distress followed; 3 hours later the general condition was greatly improved, but next day there was a large, puffy, painless swelling involving the subcutaneous tissues of the whole hand. The early and late local effects closely resembled those observed in the immediate and delayed intradermal reactions for hypersensitiveness to helminthic protein.

Treatment.—Mosquito, midge and fly bites may to a great extent be prevented by the use of dimethylphthalate. They should be treated by the immediate application of iodine, the subsequent itching being relieved by a 1 in 20 watery solution of carbolic or a 1 per cent. alcoholic solution of menthol. In bee and wasp stings, the sting should be carefully lifted or scraped out, as pressure expels the contents of the poison sac. Ammonia, alkaline soap or methylene-blue may be applied locally for the acid bee stings, and vinegar for the alkaline wasp stings. Adrenaline (min. 10 of 1 in 1000 solution) should be immediately injected subcutaneously whenever anaphylactic symptoms develop. Sepsis is treated along the usual lines.

MYIASIS

Definition.—An invasion of the tissues by larvæ of dipterous insects.

Ætiology.—Many flies deposit their eggs or larvæ in decomposing discharges, and in the tropics wounds should always be protected as well as natural orifices discharging pus or fetid material. Larvæ of special flies may develop in the nasal cavities, the ear, vagina, urethra, skin or in the intestine, and the fly *Wohlfahrtia magnifica* may deposit its eggs in the conjunctival sac with serious consequences. Two chief varieties are distinguishable—the dermal and the intestinal.

SCREW-WORM FLIES.—Two species of flies of the genus *Cochliomyia* infect man in tropical and subtropical America. The adults measure 9 to 10 mm. in length and are distinguished from the ordinary green-bottle (*Lucilia*) by the black linear

dorsal marks on the thorax *C. americana* lays its eggs in large numbers in open wounds or discharging orifices, the eggs hatch out rapidly and the larvæ generally take about 4 to 10 days for development, when fully grown they superficially resemble a screw and are about two thirds of an inch in length. They bore into healthy as well as necrotic tissue, causing great destruction locally and produce foul smelling, suppurating lesions. Nasal infection causes much pain and swelling and is often associated with a sensation of crawling, occasionally larvæ crawl out or are expelled by sneezing. They may invade the accessory sinuses, bore their way through the bones and penetrate the skull, producing purulent meningitis. The vagina and ear may also be attacked, and the middle ear destroyed. The mortality rate for nasal and aural myiasis is approximately 8 per cent. The larvæ of *Cochliomya macellaria* are often found associated in the same wound with *C. americana* as a secondary or later infection, being apparently attracted there by the foul smelling, purulent discharge, its larvæ invade necrotic rather than healthy tissue, and for this reason are of less importance medically.

Treatment—This consists essentially in covering all wounds and discharging orifices and avoiding sleeping during the day except under nets or in screened houses. Larvæ can be removed from wounds by local application of antiseptic lotions or chloroform water. In nasal myiasis larvæ may be anæsthetised by the local application of chloroform, ether or benzol on a pledget of cotton wool or by the use of an atomiser. Irrigation with 15 per cent chloroform in liquid paraffin is also effective. If the larvæ are not removed by blowing the nose or sneezing they must be removed by forceps. The accessory sinuses may need to be opened up surgically in some instances.

THE MOSQUITO WORM (Ver macaque, beef worm) (*Dermatobia hominis*)—This fly, common in Central America and adjacent parts of South America, measures 14 to 16 mm in length, has a yellow head with brown eyes, a greyish thorax and dark metallic blue abdomen. The eggs somehow become glued to the under surface of mosquitoes (particularly of the genus *Janthinosoma*), biting flies and even ticks, and in this fashion the larvæ are conveyed to the human skin where they invade the tissues via the puncture wound. A boil or warble results, containing a central opening through which the maggot breathes, discharges black excreta and later escapes to the ground where it develops into a chrysalis and finally a fly. Cattle are also affected. Hadwen and Bruce have described a remarkable anaphylactic condition in oxen and sheep infected with larvæ of warble flies (*Hypoderma bovis*, *H. lineatum* and *C. irritans*) characterised by dyspnoea, salivation, lacrimation, incontinent sphincters, vasomotor collapse, cyanosis and even death. This may be experimentally induced by injections of larval protein extracts or may result from natural trauma during life. Similar clinical features have not yet been recognised in man, though they probably occur.

Treatment—Natives kill the larvæ with tobacco juice. The opening should be enlarged with a bistoury and the maggot removed with forceps, the cavity soon heals if treated antiseptically.

VER DU CAYOR OR TUMBU DISEASE—This disease, common in Central and West Africa, is due to the larvæ of the Tumbu fly, *Cordylobia anthropophaga*, which is 8.5 to 11.5 mm long yellowish in colour, with black abdominal spots. The eggs are laid on the ground or clothing and the emerging larvæ bore their way into the tissues by means of mouth hooks. The first symptom is a pricking sensation, followed by the appearance of a boil with a central opening or warble which commonly affects the forearms, scrotum, buttocks, thighs and scalp of children and often becomes inflamed. The larva takes about a fortnight to mature and then escapes via the central hole through which its faeces were previously excreted. Sometimes the cavity suppurates. Blacklock and Gordon demonstrated an acquired local skin immunity against *Cordylobia* larvæ in guinea-pigs subjected to previous infection.

Treatment—The aperture is enlarged if necessary, the maggot squeezed out and the cavity treated antiseptically. The application of paraffin or chloroform facilitates extraction.

THE CONGO FLOOR MAGGOT—The adult fly, *Auchmeromyia luteola*, is found throughout tropical Africa, it deposits its eggs on the floors of huts and outhouses, and when the larvæ have hatched out they suck the blood of people sleeping on the ground without causing pain. The larvæ crawl actively, are 15 mm long and consist of eleven segments. The adult is orange-yellow in colour, with longitudinal dorsal stripes on the thorax, and measures 10 to 12 mm in length. Prophylaxis consists in sleeping on raised beds and the eradication of larvæ from the earth floors of infected huts.

INTESTINAL MYIASIS—Fly larvæ are common in human fæces, generally they are deposited after defecation, but sometimes they originate from the intestine, the eggs being swallowed by man in food. Many species have been described, the genera *Sarcophaga*, *Fannia*, *Apiocæta* and *Anthomyia* furnishing the majority of examples. *Fannia canicularis* accounts for most cases in Europe. Gastro-intestinal symptoms may be mild or severe and include malaise, vomiting, diarrhoea and severe griping. General toxic features may include fever, rigors, headache, thirst and vertigo, even convulsions have been described. The bile ducts may also be implicated.

Treatment.—Castor oil is generally sufficient, but thymol, filix mas, santalin and turpentine have also been recommended. If larvæ are vomited an emetic should be given.

SPIDERS

Though spiders (Araneæ) generally possess poison glands and inject venom into their prey, only a few species, mostly of the genus *Latrodectus*, are dangerous to man. Experimentally such venoms may slow the pulse and respiration, and produce tetanoid-like spasms and bronchial contraction in guinea-pigs. These red-marked spiders include *L. mactans* in America (known as the black widow), *L. hasseltii* in Australia and New Guinea, *L. geometricus*, *L. concinnus* and *L. indistinctus* in South Africa (knoppie spider) and *L. tredecimguttatus* in Eastern Europe are amongst the most dangerous species. The female often weaves its web and lays its eggs on the underside of privies, if disturbed it is liable to bite man on the genitals, buttocks or thighs during the act of defecation. The bite itself may or may not be felt as a local pricking sensation, local swelling, cedema and numbness may follow. Within a few minutes to an hour agonising severe cramping pains often set in, involving the muscles of the abdomen, legs, back and thorax. Intestinal colic due to muscular spasm may follow and in some instances paralytic ileus may supervene. Fever, sweating, respiratory embarrassment, paresthesia and sometimes priapism follow. The reflexes are hyperactive and there is increased pressure of the cerebrospinal fluid. In Peru the "pruning spider", *Glyptocranulium gasteracanthoides*, causes local gangrene, hæmaturia and neurotoxic symptoms. Kobert noted oxyhæmoglobin and methæmoglobin in the urine of persons bitten by the "cross spider", *Epeira diadema*, and Sachs found in its venom a powerful hæmolysin. Probably many other spider venoms, like zootoxins generally, exert agglutinating, hæmolytic and neurotoxic effects. The tarantulas, on the other hand, give rise only to minor symptoms, though any spider with an effective biting mechanism may produce secondary bacterial infection.

Treatment—If seen early, treatment consists in immediate ligation if practicable, incision and suction, or washing out the wound with permanganate solution. Specific antivenene, if available, is effective. Morphine may be necessary to relieve pain, and injections of calcium gluconate (10 ml of a 10 per cent solution) for laryngeal and muscular spasm. Intravenous saline and dextrose solution, and injections of nikethamide (Coramine) and pituitary (posterior lobe) extract assist circulatory failure.

CENTIPEDES

The Scolopendridæ possess poison glands which discharge at the apices of a pair of specialised claws taking the place of the first pair of legs. The small centipede gives rise only to local manifestations associated perhaps with an erysipelas-like eruption, but the tropical species, *Scolopendra gigantea*, may cause around the punctures local necrosis and lymphangitis; headache, vomiting, fever, coma and, in children, even death may follow. Treatment is similar to that of spider bites. Strong ammonia applied locally is useful.

SCORPIONS

Scorpions possess paired poison glands in the post-anal segment of the spined tail; this is thrust forward into its prey which is held in position by the formidable pedipalps. Scorpions in the tropics not infrequently kill children, and occasionally adults, and several species of the genus *Buthus* and *Centruroides*, as well as *Euscorpius italicus*, *Tityus bahiensis* and *Centruroides exilicauda*, etc., are much feared. The bite is most painful, and toxic symptoms may include fever, sweating, drowsiness, dyspnoea, vomiting, diarrhoea, muscular cramps, trismus, stiffness of the neck, muscular paralysis, respiratory failure and coma. The reflexes are hyperactive and strabismus and convulsions may occur. Haemorrhage from the gastro-intestinal tract or lungs is reported. Secondary bacterial infection is not uncommon. Local treatment may be instituted as for spider bite, and the immediate application of strong ammonia or a local injection of Novocaine and adrenaline relieves the pain. The intravenous injection of specific antivenene, prepared by inoculating scorpion venom into horse has greatly lowered the mortality rate amongst children in Upper Egypt and South America.

N. HAMILTON FAIRLEY.

E. DISEASES DUE TO SNAKES AND POISONOUS FISHES

SNAKES

Ophidiiasis or snake poisoning results from the inoculation of venom by snakes of the families colubridæ or viperidæ; non-poisonous species occasionally cause death through septic infection following their bites.

Ætiology.—Snakes are carnivorous, and Alcock and Rogers showed that even non-poisonous species may have poisonous saliva. The venom is simply a specialised secretion of the parotid (poison gland) utilised in killing and digesting prey, while the fangs are modified maxillary teeth anteriorly grooved in the colubridæ, and completely canalised in the viperidæ. The biting mechanism is vastly superior in the vipers since the fangs are longer, and capable of considerable forward rotation, whereas in the colubrines they are generally shorter and less mobile. In biting, the snake strikes with great speed, opens the jaws, rotates forward the fangs, snaps the jaws together and ejects its venom from the poison gland via the duct and fang into the tissues in one almost instantaneous movement. The vipers withdraw immediately after biting. The colubrines often hang on to the bitten part and may need to be forcibly evulsed: to inject venom effectively they must have the lower jaw fixed, and though their venoms are more poisonous the yield is, as a rule, considerably

less than that of the vipers. The toxic action of venoms is mainly dependent on (a) proteolytic enzymes, (b) phosphatidases and (c) neurotoxins. The proteolytic enzymes, so well represented in viperine venoms, digest the tissues and damage the vascular endothelium (hæmorrhagin), leading to the escape of blood and the liberation of histamine which causes extensive local œdema and gives rise to symptoms of cardio-vascular failure (Kellaway). The coagulant properties of venoms are due either to a direct coagulation of the fibrin by the venom or to the conversion of prothrombin into thrombin (Eagles). The phosphatidases cause hæmolysis and also directly affect the heart and circulation; the acceleration of venom hæmolysis by lecithin is attributed to the transformation of lecithin into lysolecithin, which is itself actively hæmolytic. The neurotoxin formed in colubrine venoms has a strong peripheral effect, paralysing the sensory, proprioceptive and motor nerve endings. Paresis of the musculature is due to the curare-like action on the motor endings and a further direct action on the muscle itself (Kellaway).

Pathology.—In colubrine bites there is a coagulative mode of death from peripheral respiratory failure, associated with fluid blood, a dilated right heart and congestion and œdema around the fang puncture. In fatal viperine bites there is hæmorrhage, thrombosis and digestion of tissue locally, associated with a spreading gelatinous œdema resembling "red currant jelly", which sometimes involves the subcutaneous tissue of the whole limb; multiple hæmorrhages are found in the viscera, serous membranes, etc. Ante-mortem clotting is present in small animals, but not in man where the blood is fluid unless, as rarely happens, the fangs enter a vein: death results from cardiac failure, peripheral circulatory failure, secondary hæmorrhage or septic infection and local gangrene.

Symptoms.—The clinical picture depends on the quantity and quality of the venom injected. Symptoms appear generally within 10 minutes to 2 hours after the bite, nausea, faintness and vomiting being characteristic early manifestations. Cardio-vascular shock follows both colubrine and viperine bites; parietic features predominate in the former, and general hæmorrhagic manifestations in the latter. In colubrine bites the fang marks are not always visible, and pain and local swelling are minimal; these features, however, are marked in the case of viper bites, which show in addition much hæmorrhagic oozing. Histamine shock probably accounts for the cold extremities, blanched, white skin, low blood pressure, vomiting, rapid thready pulse and extreme prostration. Psychological shock is sometimes an added factor, and may produce a somewhat similar picture in terrified natives bitten by non-poisonous snakes. In the earlier stages in colubrine bites the muscular weakness, ataxic gait and blurred speech may produce a picture simulating alcoholism, and diplopia, ptosis and blunting of sensation are not infrequently added; later there is inability to swallow, the tongue appears swollen, saliva dribbles from the mouth, the breathing, which was at first stimulated, becomes shallow and slow, and in fatal cases cyanosis, coma and convulsions of asphyxial origin ensue; the respirations may become costal in type and death occurs from peripheral respiratory failure. Hæmorrhagic extravasations (viperidæ) may lead to cutaneous petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia and melæna. In the early stages the gums may ooze blood and the urine contain red corpuscles.

Complications.—Blunting of the cough reflex and paresis of the muscles of deglutition may be followed by insufflation pneumonia. After krait bites an acute ascending spinal paralysis has been recorded. With viperine poisoning, local supuration and gangrene sometimes necessitate amputation.

Course.—Death may occur within 20 minutes or many days later from complications.

Diagnosis.—Generally this is not difficult, but cases may need to be differentiated from alcoholism and the bites of non-venomous snakes and scorpions. The grooved or canalised anterior fangs in the upper jaw make identification of a poisonous snake easy.

Prognosis—This depends on the amount of venom injected, the efficacy of local treatment and the availability of specific antivenene. Even with really deadly snakes, factors such as clothing, inefficient biting or a poor venom yield may prevent a lethal dose being injected, and this fact accounts for many extravagant claims regarding the value of weird cures. Most first aid measures are useless since the ligature is applied ineffectively or too late, and once a lethal dose of venom has been absorbed into the circulation, antivenene given intravenously is the only measure that will save life.

Treatment—**PROPHYLACTIC**—Snakes bite man more often by accident than design, and in snake country a little knowledge and common sense regarding the natural habits of the ophidia, the use of torches or lanterns in walking along roads at night and the wearing of strong boots and leggings would greatly lessen the incidence of snake bite. Every second case is bitten below the knee.

CURATIVE—Only two methods of treatment are of recognised value after a lethal dose of venom has been injected into the tissues. (1) Immediate ligature which delays absorption of venom, followed by such local measures as incision, excision, suction or the injection of chemicals, the object of which is to remove or destroy inoculated venom before a lethal dose can be absorbed, (2) the intravenous injection of specific antivenene. By temporarily prolonging life, effective ligature may enable antivenene to be given in otherwise fatal cases.

Local measures—The most important local measure is the immediate application of a tourniquet, as every minute's delay increases the chances of the absorption of a lethal dose of venom into the general circulation. Pressure must be applied over a single bone proximal to the heart, *i.e.* over the femur in foot and leg bites, and over the humerus in bites on the hand and forearm, in finger and toe bites a boot lace may also be tied at the base of the implicated digit. Complete stasis of the circulation has to be attained as judged by blanching of the nails and failure of incisions to bleed. Thick rubber tubing ($\frac{3}{8}$ -in) is an ideal tourniquet, but in the field, strips of clothing loosely knotted and twisted with a stick, are effective, every 20 minutes the tourniquet should be loosened for 30 seconds to flush the limb with blood. The skin should be washed with permanganate or antiseptic (if available), and if the tourniquet has been applied shortly after the bite and antivenene be not immediately available, it may be worth while making incisions over the fang punctures and then applying mechanical suction, preferably with a breast pump or a Bier's suction glass, with the object of extracting the venom from the tissues. Where ligature is inapplicable as in body bites, excision of the bitten area and washing with permanganate solution, followed by mechanical suction, is the best local treatment.

Antivenene—Whatever the local treatment may have been, specific antivenene must be given intravenously as soon as possible. Specific polyvalent antivenenes are now available for the common deadly snakes of India, Africa, South America and the United States, while monovalent antivenenes are available in certain other countries. Polyvalent antivenenes are mixtures of specific antivenenes and generally are only life saving when the venom of the particular species of snake which has bitten the patient has been utilised in their manufacture. Some antivenenes are now being put up in concentrated form in a dried state. Antivenene must always be given intravenously and the dosage varies inversely with body weight—children receiving much larger doses than adults. No patient is too ill to receive it, and even those with most severe paralysis may recover after its injection. Patients must be kept under careful medical observation as paralysis may reappear and further antivenene injections be necessary to save life. Infiltration of the tissues with antivenene in the vicinity of the bite may be useful (Fitz Simmons).

General measures—Patients must be kept warm and at rest. Black coffee and sal volatile may be given early, and injections of cortin, adrenaline or pituitary (posterior lobe) extract and of reconstituted plasma, followed by isotonic dextrose (5 per cent.) administered for circulatory shock. Nikethamide (Coramine) has value

as a respiratory and circulatory stimulant. Artificial respiration may prolong life, so permitting the administration of antivenene. It is important in cases with pharyngeal paresis to swab out the throat and keep the head low when the patient vomits; food should be withheld, and, if necessary, fluid given through a stomach-tube.

POISONOUS FISHES

In tropical waters casualties from poisonous fish are not infrequent. The effects of jelly-fish stings vary with different species; many are harmless, others produce local features such as urticaria, œdema, marked itching, burning and erythema, sometimes followed by vesicular dermatitis or actual sloughing and ulceration. Systemic symptoms may follow rapidly and include lacrimation, coryza, muscular pains, constriction of the chest, dyspnœa and cardio-vascular shock. Deaths have been reported.

Fish of the genus *Muraena* bite with their powerful, grooved teeth down which poison from the venom sac enters the tissues; many harmful species are known, and their venom may have a depressant action on both the cardiac and nervous systems.

In other fish, such as the sting-rays, there are barbs in the dorsal fin or elsewhere connected with poison glands and these may produce not only severe inflammation locally, but neurotoxic features. Tetanus organisms may simultaneously be inoculated. Certain species of *Trachinus*, such as *T. draco* found in the Mediterranean, and of *Scorpena*, such as *S. scropha* inhabiting tropical waters, are particularly dangerous, causing excruciating pain and local irritation, œdema, paralysis of the part, collapse, dyspnœa, delirium and even death within 24 hours. Septic infection may follow. Local treatment as for snake bite should be adopted. Infiltration of the tissues with procaine hydrochloride (Novocaine) (2 per cent.) is often advisable for relief of pain, and morphine also may prove necessary.

N. HAMILTON FAIRLEY.

SECTION IV

DISEASES DUE TO CHEMICAL AND PHYSICAL AGENTS

PLANT POISONS

There are more than 200 varieties of British plants which are poisonous to human beings. They may either be eaten unintentionally or in mistake for others known to be edible, and even plants grown for their food value may sometimes be dangerous. They are rarely the instruments of murder and suicide.

Some of the more poisonous belong to the Solanaceæ, including deadly nightshade (*Atropa belladonna*), henbane (*Hyoscyamus niger*), thornapple (*Datura stramonium*), woody nightshade (*Solanum dulcamara*) and black nightshade (*Solanum niger*). Berries of deadly nightshade may be mistaken for cherries, its leaves taken as dried herbs and even consumption of the meat of rabbits which have fed on the leaves has been known to cause poisoning. Suicidal attempts have been made with the seeds of henbane and thornapple. The Solanaceous plants owe their toxic effects to the alkaloids, hyoscyamus and hyoscyne, but the plants of the genus *Solanum* contain, in addition, the solanine alkaloids which are protoplasmic poisons and hæmolytic agents. These alkaloids are present in the leaves of the tomato (*Solanum lycopersicum*) and potato (*Solanum tuberosum*) and even in the tuber of the potato when methods of cultivation or storage are faulty. In epidemics of potato poisoning headache, nausea and vomiting are early symptoms, and in severe cases nephritis, hæmoglobinuria, neurological disorders or cardiac arrest may occur.

Umbelliferous plants have been responsible for many deaths because of the similarity of their roots to parsnips and their leaves to parsley. They contain the conium alkaloids which cause paralysis of motor nerve terminations and stimulation followed by depression of the central nervous system. Water dropwort (*Eranthis fistulosa*) is the most notorious, but horsebane (*Eranthis phellandrium crocata*), cowbane (*Cicuta virosa*), common hemlock (*Conium maculatum*), wild celery (*Apium graveolens*), wild parsley (*Carum petroselinum*) and fool's parsley (*Ethusa cynapium*) are also dangerous.

The most poisonous of the Ranunculaceæ is monkshood (*Aconitum napellus*) which is often mistaken for horseradish. Its action is due to the highly toxic alkaloid aconitine, which gives rise to pricking of the skin and pharynx, respiratory paralysis and ventricular fibrillation. Anemone (*Anemone nemorosa*), clematis (*Clematis vitalba*) and marsh marigold (*Caltha palustris*) are poisonous during certain seasons and the fetid helleborine (*Helleborus fœtidus*) throughout the year. The fresh sap of the marsh marigold and of the water-buttercup (*Ranunculus aquatilis*) contains anemonin, which causes vomiting, blistering and dermatitis, and the root of the Christmas rose (*Helleborus niger*) is the source of helleborein, a glycoside which has an action similar to that of digitalis but is not absorbed from the gut and results only in diarrhoea. The stems and leaves of celandine (*Ranunculus ficaria*) are also poisonous.

Senecio of the Compositæ family is the largest genus of flowering plants and in South Africa is responsible for a fatal disease of animals and humans. *Senecio lico-folius* and *S. burchelli* grow as weeds in the wheat fields and when the wheat is milled in old-fashioned mills where winnowing is inefficient their seeds are ground with the wheat grain into meal. Hæmorrhage occurs in various organs, particularly the liver, and the symptoms produced are nausea, vomiting, severe abdominal pain, hæmatemesis, ascites and jaundice. Although Senecio disease has not been described in Great Britain the toxic alkaloids have been extracted from Ragwort (*Senecio jacobea*) and other British species. Tansy (*Tanacetum vulgare*), also one of the Compositæ, was once used as an emmenagogue, ecboic and anthelmintic, and half an ounce of

the oily extract, which contains thujon has been known to cause convulsions and coma, with death in 2 to 4 hours

Poisonous plants of the Lily family include one of the autumn crocuses (*Colchicum autumnale*), wild hyacinth (*Scilla nonscripta*) and jonquil (*Narcissus jonquilla*). *Colchicum autumnale* may cause vomiting, diarrhoea, ascending paralysis and death due to the alkaloids colchicine and colchicine

Hemp, white bryony, spurge, foxglove, horse chestnut twigs and the stems and seeds of convulvulus and cuckoopint are all poisonous, and not only has death resulted from eating yew but also goats having eaten the plant have caused children drinking their milk to have gastro enteritis. Poisonous berries not already mentioned include those of honeysuckle, guelder rose, mountain ash, dwarf elder, blackbryony, yew, budcherry, sea buckthorn, snowberry, privet, berberis, mezereon, spurge laurel, common laurel and the fetid iris of the south, and at Christmas the berries of mistletoe, holly and a species of Jerusalem cherry (*Solanum pseudocapsicum*) are especially important. The seeds of laburnum, juniper and daphne and the kernels of almond are also dangerous

POISONOUS FUNGI

These include the ergot of rye and certain mushrooms which are sometimes eaten in mistake for the edible varieties

ERGOTISM—The fungus *Claviceps purpurea* grows as a parasite on rye, and in its mature form it protrudes as a spur, grey or purplish black in colour, between the leaves or glumes of the rye head. Because it is ground with the rye grain into flour, epidemics of poisoning are more common in countries such as France and Russia where rye bread is a staple article of food. Ergot contains at least ten alkaloids including ergotoxine, ergotamine, ergometrine and a number of bases including histamine and tyramine. They are present in varying proportions, which accounts for the complexity of the clinical picture of poisoning

Symptoms—The onset of the illness is usually gradual over a period of weeks or months, although in some cases it is rapid with premonitory symptoms for only 2 or 3 days. These include nausea, vomiting, diarrhoea, headache, vertigo and lassitude. Paræsthesiæ described as tingling, pricking, itching or numbness are characteristic. In the *gangrenous type* of ergotism there are severe pains, paræsthesiæ and swelling of the extremities followed by gangrene of the fingers and toes. In the *spasmodic type* painful muscular contractions seize the limbs, and the fingers and toes are powerfully flexed and adducted. The posture may resemble tetany, with which the condition is sometimes confused. The patient may be thrown to the ground when the spasms are generalised and they may assume a convulsive or *epileptoid form*. Absent knee- and ankle jerks, ataxia, impairment of sensibility and loss of pupillary reaction to light are found in the *tabetic type*. Lower motor neurone lesions, cervical sympathetic paralysis, loss of upper limb reflexes and hypoaesthesia in the cervical and dorsal regions have also been described. There is often a toxic psychosis causing either excitement or hypomania with hallucinations and delusions, or anxiety, melancholia and stupor. Uterine hæmorrhage or abortion may complicate pregnancy

Prognosis—In acute poisoning the outlook is good, although old and debilitated patients may die from cardio-vascular collapse or following severe and prolonged spasms. Permanent sequelæ include loss of fingers and toes from gangrene, hemiplegia, dementia and visual impairment due to cataract formation

Treatment—Atropine is sometimes an effective antidote. Sedatives may be required when there are mental symptoms

POISONOUS MUSHROOMS

Amanita phalloides and *Amanita muscaria* are the most important poisonous mushrooms

(a) *Amanita phalloides*.—This contains the deadly substance, phallin or amanita toxin. The susceptibility of children is greater than that of adults. The ingestion even of part of a plant may result in poisoning and the mortality rate is high. After a prodromal period of 4 to 24 hours, acute abdominal pain, vomiting and diarrhoea occur. The vomit and stools may contain blood and mucus. Anuria may occur. Short periods of remission may follow, but usually within a day or two jaundice, cyanosis and coldness of the extremities develop. In fatal cases coma supervenes. When poisoning is less severe, the symptoms abate in about a week and the patient is well within 4 weeks.

(b) *Amanita muscaria*.—This contains muscarine. After a small dose the patient becomes mildly excited, and the fungus is used by Siberian peasants to induce drunkenness. After larger doses the first symptoms appear within 2 to 6 hours. They are salivation, sweating, retching, vomiting and diarrhoea. Giddiness, confusion and hallucinations rapidly follow, and the pupils become contracted and fail to react to light or on accommodation. Amaurosis and diplopia may occur. Although the symptoms are violent the mortality rate is low. In all cases of mild poisoning the prognosis is good.

EFFECTS OF TOBACCO

Tobacco is obtained from the dried and cured leaves of *Nicotiana tabacum* L. It derives its botanical name from the island of Tobago and from the name of the French diplomat Nicot, who introduced it into Europe at the end of the sixteenth century. In the three forms smoking, chewing and snuffing, tobacco is now indulged in by many millions of people throughout the world.

Ætiology.—Tobacco smoke contains nicotine, collidine, lutidine and other pyridine bases, furfural, acrolein, methyl alcohol and various volatile oils. Carbon monoxide and hydrocyanic acid are present in concentrations too low to be significant. There is no evidence that the lead and arsenic contained in insecticidal sprays used on tobacco plants contribute to the ill effects of tobacco smoking.

Symptoms.—Certain ill effects occur from handling the tobacco plant and its products in factories.

Acute nicotine poisoning, usually mild, may follow heavy smoking by a novice. It may occur also in a new worker who handles the leaves in curing tobacco. One fatal case took place in a workman employed in steeping tobacco in water. Gardeners and vine growers have been affected after using insecticidal sprays containing nicotine. The features of poisoning are pallor, faintness, sweating, nausea, vomiting, diarrhoea, bradycardia and hypotension.

In moderation tobacco smoking gives rise to a feeling of ease and relaxation, and some habitués claim to work better while smoking, although in the majority there is a lessening of efficiency. Some of the effects are neither pleasurable nor harmless, and the more important of these are described below.

Cardio-vascular.—Elevation of the blood pressure is commonly observed, and in certain patients excessive smoking may cause sinus tachycardia, premature contractions, paroxysmal tachycardia and rarely paroxysmal auricular fibrillation. Lowering or inversion of the T waves of the electrocardiogram has been demonstrated in a proportion of smokers who are normal subjects, and when coronary artery disease is present, attacks of angina pectoris may be precipitated. Most patients with thrombo-angitis obliterans are heavy smokers and less than 10 per cent. are non-smokers, but the ætiological connection is far from clear. Since smoking causes peripheral vasoconstriction and lowering of skin temperature, it should also be avoided by those with Raynaud's phenomenon.

Respiratory.—In cigarette cutters employed in factories the local irritation of

tobacco dust may cause asthma. The chronic laryngitis and pharyngitis of heavy smokers which causes smoker's cough is probably due to inhaled irritating pyridine bases. Bronchitis is commoner in smokers than in non-smokers. It has also been shown that there are more heavy smokers and fewer non-smokers among patients with lung cancer than among patients with other diseases, and the incidence of both bronchitis and lung cancer increases significantly with the amount smoked.

Gastro intestinal—Squamous carcinoma of the lip may occur from the chronic irritation by tobacco and heat of pipe smoking, especially in the case of clay pipes. Some heavy smokers partially lose the sense of taste. The relationship of smoking to peptic ulceration is indefinite. In general it causes loss of appetite and lessening of gastric motility, factors which increase the symptoms of gastric ulceration and delay healing. The effect in duodenal ulceration is not so uniform, the pain sometimes being relieved by smoking. It is clear that smoking decreases the effectiveness of treatment and increases the tendency of peptic ulcer to relapse. Systematic experimental studies have shown that smoking increases the motor activity of the colon, hence the mild laxative effect experienced by many habitual smokers.

Skin—In factories, tobacco dust affects especially beginners, causing irritation of the eyelids and conjunctiva with lacrimation. The dust or juice from the leaves may cause dermatitis on the back of the hands and face. The genitalia may become affected where the dust is conveyed by unwashed hands.

Nervous system—In heavy smokers, in those who chew tobacco and in those exposed to tobacco dust in factories, tobacco amblyopia is a rare complication. The hazard is greater in pipe smokers than in cigarette smokers and especially affects those who use shag and other strong tobaccos. The patients are between 35 and 55 years of age and complain of blurring of vision, especially in bright daylight. The condition is bilateral, though often worse in one eye. There is a scotoma in the first instance for red between the blind spot and the fixation point, which extends to involve the fixation point, leaving peripheral vision intact. This is followed at first by temporal pallor of the optic disk and later by optic atrophy. The condition is primarily retinal and results from degeneration of ganglion cells, especially in the macular area.

Prognosis and Treatment—Tobacco smoking is contraindicated in tobacco amblyopia, thrombo angustis obliterans and gastric ulcer. As indicated by the incidence of amputations, thrombo angustis obliterans is less severe and more amenable to therapy in those patients who give up smoking early and completely. Treatment of tobacco amblyopia consists in total abstinence from tobacco. Insistence on this always leads to improvement and may save the patient's sight. In duodenal ulcer and in angina of effort it is unfair to demand abstinence from smoking unless there is clear evidence in the patient concerned that this brings on the attacks.

Prevention of acute nicotine poisoning in tobacco curing factories is achieved by providing rubber gloves for all workers who must handle the tobacco leaves. Where a factory worker, gardener or horticulturalist gets the juice of tobacco leaves or a solution of nicotine on the skin, the use of hot water must be avoided, otherwise absorption will be facilitated. Prevention of asthma in the manufacture of cigarettes turns upon mechanisation, which must include enclosure of machines in such a way as to avoid contamination of the working environment with tobacco dust.

The tobacco habit is difficult to break. The abstinence symptoms are mainly craving and restlessness, none of the profound constitutional symptoms found on withdrawal from addiction to narcotics is seen. The patient must have the courage and determination to abstain completely, and it is better that he should not try to decrease the amount of tobacco gradually. On occasions treatment may include a mouthwash containing 1 per cent of copper sulphate in order to render the taste of tobacco smoke extremely unpleasant at least for an hour or so.

DONALD HUNTER

EPIDEMIC DROPSY

Synonym.—Argemone Poisoning

Definition.—A condition characterised by œdema, vascular changes and cardiac insufficiency, resulting from the ingestion of the seeds of the Mexican poppy (*Argemone mexicana*) or their products.

Ætiology.—Epidemic dropsy is most commonly seen in India, especially in Bengal, Bihar, Orissa and the Central and United Provinces. It has been recorded in Mauritius, Fiji and South Africa.

The toxic agent, which has not yet been identified, is contained in the seeds of the Mexican poppy which sometimes grows as a weed amongst the mustard or wheat crops. The seed is very similar to the mustard seed, and may be mixed with the latter accidentally or deliberately as an adulterant in the manufacture of mustard oil, which is widely used for cooking in many parts of India.

The incidence of epidemic dropsy in India depends to some extent on the issue of the first season's oil; there is some evidence that the toxicity of the oil may be reduced during storage. It is highest during the rains or soon after, *i.e.*, in July and August, and lowest in April.

Breast-fed infants and children under 4 years of age are not often affected, presumably because they do not have access to the oil. All other age groups may be affected. The racial distribution of the condition depends on dietetic habits. Wherever mustard oil is eaten and there is a possibility of contamination, epidemic dropsy may appear. The appearance of the syndrome is independent of the presence of rice in the diet. It appeared in South Africa in individuals after eating flour made from badly sieved wheat. It is probable that malnutrition and deficiencies may be conditioning factors, especially in those, such as rice eaters, who live on a high carbohydrate diet.

Pathology.—There is a generalised acute vasodilatation, affecting the capillaries and small vessels, especially of the skin, heart muscle and uveal tract. Irregular formation of new blood vessels takes place, particularly in the subcutaneous tissues. In some cases hæmangiomas (so-called "sarcoids") develop and may become small pedunculated tumours which bleed readily. Hæmorrhage may also occur from mucous membranes. There may be some secondary normocytic orthochromic anaemia.

Vasodilatation in the iris and ciliary body commonly leads to raised intra-

are common. The electrocardiogram may show evidence of myocardial damage, with sinus tachycardia and extrasystoles. Acute heart failure may develop with fibrillating muscle and irregular pulse, and enlarging tender liver. Fatal heart insufficiency may develop steadily or appear suddenly.

Peripheral vascular changes are present in most cases. Dilated vessels give the skin an irregular bluish mottled appearance, which may be present from the onset in severe cases, or develop after the œdema in moderate cases. Subcutaneous telangiectases or hæmangiomas become visible in some patients. The latter may develop into small tumours or "sarcoids" up to half an inch across and raised above the surrounding skin or sometimes sessile. Sarcoids bleed freely if injured; they gradually reduce during convalescence. Hyperæsthesia, tingling of the skin and tenderness of the calf muscles are prominent signs in some cases. The knee jerks may be absent. General effects vary. There may be mild fever. Nausea is the rule and there is often vomiting. Watery diarrhoea is common.

Glaucoma is one of the most serious complications. In some outbreaks up to 10 per cent of those affected may exhibit raised intraocular tension, with or without local pain and associated with dimness of vision and contracted visual fields.

Course and Prognosis.—In the average case the signs, especially those related to the cardio-vascular system, subside upon rest in bed and are exacerbated on exertion. In some cases the cardiac signs are progressively severe and fail entirely to respond to treatment, the patient dying from cardiac failure in a few days.

The death-rate is usually about 5 per cent but varies from outbreak to outbreak, reaching as high as 50 per cent.

Prognosis in the individual case should be guarded. It depends chiefly on the cardiac state. It is bad where there is decompensation. Serious cardiac failure may develop at any stage.

Diagnosis.—Diagnosis is easy in a recognised outbreak but may be difficult in isolated cases. A knowledge of the patient's diet is essential.

Acute œdema appearing in several members of a family or of a community known to use mustard oil is highly suggestive. Wet beri-beri, and famine œdema may cause confusion. Information about the diet, or lack of it, is important in differentiating epidemic dropsy from these conditions, which usually develop more slowly. In the former there may be prominent associated nervous signs and a vigorous response with diuresis to thiamin therapy. Both may occur concurrently with epidemic dropsy.

Treatment.—Rest in bed is essential. Mustard oil or other possible sources of the toxic agent should be excluded from the diet.

In diarrhetic cases an initial saline purge may be given. The cardiac insufficiency may or may not respond to digitalis. A combination of ammonium chloride and mersalyl may help.

Dietary deficiencies should be adjusted. Vitamins A, B, C and P may be required, and can be supplied most easily in the form of vegetable extracts, cod-liver oil and fruit juices. Epidemic dropsy, unlike beri-beri, does not respond to vitamin B₁. The salt intake should be limited in the acute stages.

Bleeding from hæmangiomas can be controlled by pressure. Glaucoma requires operative treatment. It does not usually respond to eserine. Convalescence is slow.

BRIAN MAEGRAITH

Three species of *Lathyrus* may be associated with poisoning in man (1) *Lathyrus sativus*, known in India as Khesari dal, (2) *Lathyrus cicera*, the dwarf chick-pea found in France, Italy and Algeria, and (3) *Lathyrus clymenum*, found in Spain, North Africa and the Levant. It is solely confined to countries where different kinds of chick pea are used for food, but the causative principle is unknown. Young people are specially liable, and men are more affected than women. It occurs as an epidemic amongst the poorest classes in times of great scarcity, when bread is made from a mixture of pea and wheat flour. It may also be eaten as porridge, or the peas may be boiled with oil and then consumed. Formerly it was attributed to the grain of *Lathyrus sativus* (Khesari dal) but in India, Howard, Anderson and Simonsen failed to demonstrate any poisonous principle. They succeeded in isolating two toxic alkaloid like bases, vicine and divicine from *Vicia sativa* (akta), an allied vetch, the seeds of which were a common contaminant of Khesari dal and produced symptoms of lathyrism when fed to ducks.

Pathology—A chronic sclerosis is found in the spinal cord involving the posterior and lateral columns. Possibly a toxic spasm of the arteries of the cord, followed by thrombosis, is the basis of the condition.

Symptoms—The onset may be insidious with backache, burning pains and weakness of the legs, or it may be sudden, as when after a hard day's work in the rain the patient wakes up with stiff, weak and trembling legs, which feel heavy to lift. These symptoms increase rapidly, and in 10 days walking may be impossible without the aid of a stick. Both legs are usually affected simultaneously, first the calves, then the thighs. Gradually a peculiar gait develops, the patient laboriously progressing by means of a two handed staff, "the leg bearing the weight of the body is bent at the knee and trembles, while the advancing limb dragged wearily forward and strongly abducted, is planted unsteadily directly in front of its fellow, the toes reaching the ground first." When lying on the back, spasm of the adductors ceases and the knees can be separated. There is little or no atrophy or loss of muscular tone, the knee jerks are increased and ankle clonus is marked. Sensation is normal. Incontinence of urine and faeces and possibly loss of sexual power follow involvement of the lumbar segment, but the upper extremities are rarely implicated.

Diagnosis—The occurrence of multiple cases simultaneously and the history of eating chick peas as food confirm the diagnosis.

Prognosis—This depends on the stage at which the case is diagnosed, if early great improvement follows treatment, but in later cases when the cord has become permanently damaged spasticity persists.

Treatment—Varieties of chick pea must be avoided as human food, and their abolition stamps out the disease. Avoidance of damp and wet ameliorate the symptoms. A generous diet adequate in vitamins should be given. Massage and electricity are indicated.

ACKEE POISONING

Synonym—Vomiting sickness of Jamaica

Definition—A frequently fatal disease, especially affecting children in the West Indies characterised by vomiting and nervous symptoms due to eating the unripe ackee fruit.

Ætiology—Ackee fruit grows on the tree *Blighia sapida* (Sapindaceæ) in the West Indies and West Coast of Africa. The mature fruit is harmless but when eaten in an immature state before the fruit opens it proves a deadly poison, especially if soup be made from it or other ingredients like rice be boiled in ackee water. The poison is contained in the aril of the unripe fruit.

Pathology—Intense fatty changes are found constantly in the liver and to a

lesser degree in the kidneys, heart and cortical brain-cells. Hyperæmia of the meninges and other organs occurs, also hæmorrhages in the viscera.

Symptoms—The patient, who is generally a healthy child, suddenly commences vomiting some 2 hours after a meal containing unripe ackee fruit and complains of nausea and abdominal discomfort. After 3 or 4 hours of sickness a calm interval ensues, followed by nervous symptoms, including cerebral vomiting, twitching of muscles, convulsions and coma.

Prognosis.—Once nervous symptoms supervene the condition is invariably fatal, the average duration being 12 to 14 hours.

Treatment—Prevention consists in discarding the immature unopen fruit and in not utilising the water in which ackee fruit is boiled as soup. Alcohol precipitates the poison, and the immediate administration of rum or ether and ammonia as advocated by Scott has reduced the mortality in school children from 90 to 27 per cent.

N HAMILTON FAIRLEY.

ACUTE MORPHINE POISONING

Under this heading can be included poisoning due to opium, diamorphine (Heroin) and Dilaudid, for the picture in each case is similar. (For Chronic Morphineism, see p 1640.)

Ætiology—Poisoning occurs by accident or suicide, after ingestion or injection, though cases have followed rectal administration or absorption through wounds. The fatal dose is variable, of morphine, probably gr 2 to 3 is needed, and of opium gr 10 to 30, though less in some cases. Tolerance is easily established, but conversely children are unusually susceptible. The fatal period is from 6 to 12 hours, regardless of the dose.

Pathology—Death is from respiratory failure, and necropsy reveals cyanosis of the head and extremities and dark blood. There may be a smell of opium in the stomach, and demonstrable quantities of the drug in the urine and organs.

Symptoms—In 10 to 30 minutes if the drug was taken by mouth, or less if by injection, a transient phase of euphoria and exhilaration may be seen, then nausea and vomiting, later dizziness, heaviness in the head and sleepiness, soon resulting in coma. The patient in coma shows slow stertorous respiration at 2 to 4 per minute, with cyanosis of the face, slow pulse, general flaccidity and loss of reflexes, perhaps an extensor plantar response and pin point pupils. Sweating is considerable and the skin is warm in spite of a low temperature. Oliguria, pruritus and skin rashes are sometimes seen. The pupils dilate in the ultimate stage of respiratory failure.

Diagnosis—Coma, stertor and constricted pupils are a suspicious triad. Pontine hæmorrhage finally shows a rising temperature.

Treatment—Warmth, oxygen and artificial respiration are needed, then a stomach wash, first with water, preserving the stomach contents, then with potassium permanganate solution, gr 5 to 10 to the pint with charcoal suspension. Gastric lavage is used, and repeated, even if the drug has been injected. Nalorphine (Lethidrone) is an antagonist to drugs with a morphine like action and it has proved an effective antidote to morphine, pethidine (Demerol) and methadone (Physeptone). It can be given intravenously, intramuscularly and subcutaneously in repeated doses of 10 to 40 mg. Its action is specific for the morphine derivatives and similar compounds, and it should not be used in coma due to other depressants.

Apart from acute poisoning, an individual idiosyncrasy is sometimes seen, in particular in the very young and the very old, and in allergic persons. Such patients often vomit and they may show tremor, and even delirium and convulsions. It is dangerous to use morphine in cases of head injury, raised intracranial pressure, myxœdema and bronchial asthma.

COCAINE POISONING

Cocaine is obtained from the leaf of *Erythroxylum coca*; it is expensive and its habitués tend, therefore, to be wealthy psychopaths.

Ætiology.—The drug is most commonly met as a white powder, known to the underworld as *snow*, and taken as snuff; it can be injected or taken by mouth. A tolerance may be established, though not as high a one as in morphinism. Its chief delight is the speed with which it relieves fatigue; it temporarily enhances mental and physical vigour, being a true cortical stimulant.

Symptoms.—The patient suffers digestive disturbances and remarkable anorexia, dispenses with food and becomes emaciated. He complains of salivation and of formication or else a sensation of sand grains under his skin. There may be convulsions, hallucinations, delirium or even mania. He is usually unpleasant to others, his behaviour alternating between exaltation and dejection, with a lowered moral tone and a proclivity to sexual excesses. He may have dilated pupils and sparkling eyes, tremor, nasal inflammation, ulceration or even perforation of the septum, or otherwise the tell-tale scars on the forearms of old sites of injection. He takes the drug for its stimulant effects and not to ward off withdrawal symptoms, which are slight.

Treatment.—Though the habit is not so compelling as morphinism, and withdrawal symptoms are less, the discipline of an institution is needed. The drug is abruptly stopped, and sometimes hyoscine by mouth is given as a temporary substitute.

ATROPINE POISONING

Atropine occurs in such solanaceous plants as *Atropa belladonna* (deadly nightshade) and *Datura stramonium* (thornapple) together with hyoscine and hyoscyamine, the toxic actions of which are similar.

Ætiology.—Children are susceptible and apt misguidedly to eat the berries or seeds of these plants. Intoxication has occurred in using the drugs therapeutically, even in ophthalmology, but homicidal and suicidal cases have been few. Individual idiosyncrasy, revealed as a local reaction to atropine eye-drops, or as a general erythema and pyrexia, is not uncommon. The fatal dose is uncertain, but quantities of the order of gr. $\frac{1}{4}$ to 2 of pure atropine or 14 belladonna berries have been quoted.

Symptoms.—These appear quickly: there is a dry burning mouth, intense thirst and difficulty with talking and swallowing; the skin is dry and flushed, vision is blurred and photophobia present. The temperature rises and a state of excitement follows, suggesting acute mania or alcoholism, with obstreperous behaviour, disorientation and hallucinosis. This picture may persist for some hours, or may in more severe intoxication give place to a stage of depression, when the victim is quiet and lapses into coma, dying from respiratory failure. Fatalities are rare.

When examined in the earlier stages, the patient has dilated fixed pupils, a red dry skin, tachycardia, pyrexia and rapid respirations, perhaps a generalised erythematous rash; tremors and convulsions have been noted. Such signs may persist several days into convalescence, when there is mental confusion and loss of memory.

ALCOHOLISM

Alcoholism is dealt with in this section mainly from the point of view of the physical effects. The subject may be conveniently divided into (1) acute alcoholism, (2) alcoholic coma, (3) dipsomania and (4) chronic alcoholism. The section of Psychological Medicine (p 1637) should also be consulted.

1 ACUTE ALCOHOLISM

Synonyms—Acute Alcoholic Poisoning, Drunkenness

Definition—A person is said to suffer from acute alcoholism when as a result of alcohol he is unable to do with safety to himself or others that which he attempts.

Ætiology—The effect of alcohol varies in different individuals and depends not only on the amount taken but also on the physical state and mental stability of the patient.

Pathology—Repeated sublethal doses cause no pathological changes in experimental animals. However, alcohol enhances the effects of other poisons and accelerates such degenerative processes as atheroma. Clinical observations on healthy human adults support these findings. It is a matter of common experience that post alcoholic intestinal symptoms, malaise and headache are more apt to occur when some other poison is taken at the same time. Examples are tobacco and the harsh acids of badly prepared wines. In alcoholic intoxication the blood and urine alcohol reach a level between 0.1 and 0.3 per cent. The basal metabolism is raised, and there is great water loss from over breathing, sweating, diuresis and sometimes vomiting. Alcohol depresses nervous activity. Reaction time is prolonged and perception dulled. The special senses become less acute, weakness of accommodation and of ocular synergia occur with blurred vision and diplopia. The normal social inhibitions become dulled so that the animal tendencies escape repression, with consequent non social or even anti social behaviour. Indeed this lessening of inhibition is the end aimed at in taking alcohol, and allows a certain freedom and exhilaration in over repressed persons. This escape from inhibition should not be regarded as an increase in general efficiency. In unstable persons pathological mental tendencies may become uncovered, with resulting epileptic attacks either in the form of fits, or as "epileptic equivalents" such as *mania a potu* or automatism (see p 1637).

Symptoms—The clinical picture of drunkenness is well known. After sleeping the patient awakens with headache and the usual symptoms of a mild gastro intestinal upset. As has been inferred before, there is little after effect in the healthy person who drinks sensibly. People who have drunk unwisely or have taken too much tobacco will feel ill all the next day. They show the clinical picture of a mild melancholia with gloomy thoughts, poor volition and excessive irritability. Strong sensory stimuli are poorly tolerated. Mental concentration is poor, and there is marked lessening of general efficiency.

Diagnosis—It is often impossible for an exact diagnosis to be made until the patient has been kept under observation and this precaution should be taken where there is any doubt. No exact percentage of alcohol in the blood and urine can be fixed as the precise limit between sobriety and drunkenness for medico legal purposes.

Prognosis—Recovery usually takes place within 24 hours and can be hastened by appropriate treatment.

Treatment—If the drunken person is seen before going to sleep he should be given an emetic of warm sodium bicarbonate solution (gr 60 to a pint) and subsequently encouraged to take a drink of water. The aim of this treatment is to remove any of the poison that remains in the stomach, to soothe the mucosa and to combat the dehydration. If the patient needs treatment and refuses it apomorphine gr $\frac{1}{2}$ or gr $\frac{1}{10}$ hypodermically will induce vomiting within a few seconds and leave the

glassy or watery. The conjunctivæ are red. His appetite is poor, and he has a preference for spicy and pungent foods. He rarely takes any breakfast, and does not feel himself until he has had a drink. On rising he clears his throat of much viscid mucus, which he usually refers to as "my catarrh". Often the hawking induces an attack of vomiting. Cases with much gastric catarrh vomit either on rising or at a fixed time afterwards. He is usually proud of the freedom of his bowels, but when careful inquiry is made it is found that he has diarrhœa. Night-rising once or twice is common. The majority of cases have attacks of paræsthesia in the limbs from time to time, and on examination the reflexes are found sluggish and the calves tender. In the presence of arterial degeneration a cerebral vascular accident may occur at any time, but more frequently the final illness is uræmia.

Neurological complications.—Some degree of peripheral neuritis is common (see p. 1589). *Korsakoff's psychosis* may be present (see p. 1638). Sometimes in alcoholic neuritis the pupil is very sluggish to light. In such cases, if the neurological signs overshadow the mental, the condition is often referred to as *alcoholic pseudo-tuber*; if, on the other hand, the mental signs predominate over the physical, it may be called *alcoholic pseudo-paresis*. These terms are self-explanatory. *Acute hallucinosis* or the more serious *delirium tremens* are acute psychoses and are dealt with in the section of Psychological Medicine (see p. 1638).

Prognosis.—(a) **GENERAL.**—As regards cure this is often bad. In many cases, however, suitable management leads to a good all-round improvement. Intercurrent diseases, especially those of the respiratory system, are poorly tolerated. Pneumonia and tuberculosis have a much worse prognosis in these patients than in normal people. Anæsthetics are taken badly, and there is more likelihood of post-anæsthetic complications.

(b) **NEUROLOGICAL.**—This has been greatly altered for the better since the true nature of these complications has been understood, namely, that they are due to deficiency of vitamin B₁. Provided that no permanent damage has been done, cure can now be obtained of both the neuritis and the Korsakoff syndrome.

Treatment.—(a) **OF THE CHRONIC ALCOHOLISM.**—This is difficult, and usually disappointing in the hands of the general physician. The underlying causes are mental and these need the attention of experts. Should it be necessary to treat the patient in his own home without a psychiatrist the friends should be spoken to earnestly, and everyone in contact with the patient must be above suspicion, because absolute withdrawal of alcohol is essential. Since the patient has been used to this nerve depressor, he may experience severe withdrawal symptoms and some simple sedative such as paraldehyde min. 120 should be available. Where paraldehyde is not tolerated, soluble barbitone (Medinal) gr. 7½ is suitable. The patient's appetite will be poor, and may be encouraged by a simple stomachic before meals. After meals he should be given a sedative alkaline mixture, such as bism. carb. gr. 15, sodii bicarb. gr. 15, tr. bellad. min. 10, tr. card. co. min. 120, aq. menth. pip. ad min. 240. He should be handled sympathetically, and any outstanding domestic difficulties and worries resolved. Graduated doses of strychnine are employed in many cases. Such treatment acts by suggestion. Better results will be obtained in these patients if at the beginning they are put to bed for a few weeks, and if the gastro-intestinal illness is treated intelligently. For psychological effect, the patient may be put on a rigid diet with all the quantities carefully prescribed and supervised. The form of the diet will depend on the circumstances, but it should be bland, well balanced and rich in vitamins.

(b) **NEUROLOGICAL.**—Rest the affected parts, including the mind, and give large doses of vitamin B₁ (aneurine hydrochloride, thiamine hydrochloride). For the first 2 weeks, 10 mg. should be given intramuscularly every alternate day, and thereafter, twice weekly. In addition, 30 g. of brewer's yeast should be given by mouth twice daily. After recovery the patient should continue to take vitamin B₁ indefinitely.

METHYL ALCOHOL POISONING

Methyl alcohol or methanol is a clear colourless, volatile, inflammable liquid with a burning taste and an odour somewhat resembling that of ethyl alcohol.

Ætiology.—It is used in anti freeze for motor car radiators, as a denaturant of ethyl alcohol, as a solvent for paints, varnishes, shellacs and paint removers, and in dry cleaning. It is employed also in the manufacture of formaldehyde, synthetic indigo, explosives, felt hats, shoes and linoleum. Outbreaks of poisoning can be expected when alcoholic drinks contaminated with methanol are illegally distributed, and it should be remembered that certain patients with chronic alcoholism are addicted also to methyl alcohol. Poisoning in industry, by inhalation of the vapour or its absorption through the skin, may occur when methyl alcohol is used as a solvent, especially in spray painting. This was at one time common in the U.S.A., but it has almost disappeared since that country adopted denatured ethyl alcohol as a safe substitute.

Pathology.—Acidosis is a feature of all severe cases and the plasma-bicarbonate level is often below 20 meq/l. In the body methyl alcohol is partly oxidised to formaldehyde and formic acid, and it has been suggested that these toxic substances inhibit certain oxidative processes in the cells, possibly by combining with iron in the respiratory oxidase. Carbon dioxide is not formed and organic acids accumulate, which accounts for the extreme acidosis. It has been observed that drinking ethyl alcohol can prevent or delay the toxic effects of methanol. The ethyl alcohol competes successfully with it for the available alcohol dehydrogenase in the liver, and the oxidation of methyl alcohol cannot proceed until all the ethyl alcohol has been metabolised.

Symptoms—There is usually a latent period of about 24 hours before the onset of symptoms, these include headache, dizziness, anorexia, nausea, weakness and visual disturbances. The trouble with the eyes begins usually with pain in the eye-balls and tenderness on pressure, slight photophobia and then indistinct vision with dancing spots, snowstorm effects or flashes before the eyes. If loss of vision progresses there is concentric constriction of the fields both for form and for colour. Severe headache is rapidly followed by blindness, delirium, stupor, acute mania with retrograde amnesia, coma, convulsions and death in respiratory failure. In industrial cases there is often irritation of the skin, and, when the concentration of methyl alcohol inhaled is very high, the worker may suffer a degree of poisoning equal to that when it is taken by mouth.

Physical signs—The patient is apprehensive and the skin cool and cyanosed, with profuse perspiration. The pupils are dilated and react sluggishly, and ophthalmoscopy sometimes shows hyperæmia of the optic disk and retinal oedema.

Treatment—In severe cases an immediate intravenous infusion containing sodium bicarbonate can be life saving. Sixty to 70 g. may be required in the first instance, but the exact amount should be decided on the results of serial estimation of the alkali reserve or the pH of the urine, because over treatment leads to tetany, hypokalaemia and sodium retention. Small amounts of ethyl alcohol can be given 4-hourly.

CARBON MONOXIDE POISONING

Carbon monoxide, or carbonic oxide (CO), is a very poisonous gas. If present in the air breathed in an amount equal to 0.2 per cent. it is capable of destroying life, while an atmosphere containing 0.05 per cent. of carbon monoxide gives rise to definite symptoms of poisoning.

Ætiology and Pathology.—When carbon is burnt in a limited supply of oxygen, carbon monoxide is produced in varying amount. *Domestic poisoning* Charcoal

fires and braziers as well as coke furnaces give rise to considerable amounts of CO. Certain types of water heaters and slow combustion stoves are common sources of production of the gas, which may give rise to poisoning if the ventilating flues are inadequate. The exhaust fumes from motor-cars and petrol-burning engines contain approximately 6 per cent. of carbon monoxide. Diesel engines are widely used in motor-buses, lorries and tractors. When a diesel engine is run on a high fuel-air ratio, carbon monoxide is produced in amounts comparable to those from a petrol engine burning a rich mixture. The commonest source of carbon monoxide poisoning is from coal gas which is used for illuminating or heating purposes. Coal gas contains normally from 4 to 10 per cent. carbon monoxide, and it often approximates to the latter figure. It is a common cause of death either from accidental leakage from pipes or from purposive exposure due to turned-on taps. Carbon monoxide occurs in the smoke and fumes from fires with inadequate chimney ventilation. It is important to remember that the products of combustion of gas stoves and gas fires contain an appreciable amount of carbon monoxide and the flues from these must be adequate completely to carry away the products of combustion. *Industrial poisoning*: This occurs from the fumes from blast furnaces, in iron smelting, and in blasting operations in mines. In coal mines the explosions from coal dust, or inflammable gases, lead to the production of carbon monoxide (after-damp). *Water gas* is prepared by passing steam over red-hot coke, and contains upwards of 30 per cent. CO. It is used for heating purposes, and is sometimes added to coal gas before its distribution. It is very poisonous and, owing to its slight smell, is very dangerous unless mixed with odorous gases. *Producer gas* is prepared by passing a mixture of steam and air over red-hot coke in retorts. It is used for heating the coal retorts for the preparation of coal gas. Producer gas is a mixture of carbon monoxide, hydrogen and nitrogen, and is similar in composition and properties to water gas, and may contain as much as 30 per cent. of carbon monoxide. Industrial dangers also arise from leakages in the plant and from the process of charging the producer-gas retorts.

Action of carbon monoxide.—Carbon monoxide has 220 times the affinity for hæmoglobin that oxygen has. If respired, it will, therefore, more or less completely displace the oxygen from its combination with the hæmoglobin of the red cells. This prevents oxygen being carried in requisite amount by the red cells to the tissues of the body, which thus become deprived of the oxygen necessary for their vital functions. The extent to which the hæmoglobin is saturated with carbon monoxide depends upon the percentage of the latter in the air breathed. When the hæmoglobin becomes one-third saturated with carbon monoxide, definite symptoms of poisoning occur, and when the saturation exceeds 50 per cent. there is grave danger of a fatal issue. It is important to note that carbon monoxide is a tissue poison. It does not act simply as an oxygen depriver to the tissues, but undoubtedly has in addition a narcotic action upon them. This is best illustrated by considering the serious symptoms of narcosis (muscular paralysis and loss of consciousness) which occur in a person in whom 50 per cent. saturation of the hæmoglobin with carbon monoxide exists. These symptoms far exceed in gravity those of a person possessing only 50 per cent. of hæmoglobin as the result of anemia from disease or hæmorrhage. Carbon monoxide acts as a tissue poison especially to the nervous system, but there is evidence to show that it acts on all the tissues of the body, notably the cardiac muscle, and may

rhages beneath the pericardium. In some cases of carbon monoxide poisoning putrefaction is much delayed.

Symptoms—Carbon monoxide is odourless and any smell of an atmosphere containing it is due to the presence of other gases or vapours having a characteristic odour. It may be respired freely without any irritation to the air passages. Premonitory symptoms are giddiness, ataxic gait, a swimming sensation, headache or a sensation of heaviness or constriction in the head, noises in the ears and a feeling of oppression in the chest. Sometimes nausea and vomiting occur. The onset is, however, often sudden, and this is likely to be so when the percentage of carbon monoxide is relatively high. In these cases, the first symptoms may be sudden collapse, with loss of consciousness, and this is associated with complete loss of power in the limbs. In subacute cases the symptoms may resemble those of acute alcoholic poisoning.

The blood pressure rises at first, and the pulse is full and may not be increased in rate. Muscular weakness and drowsiness quickly supervene in severe cases, and the patient falls unconscious. In the condition of coma the blood pressure falls and the pulse becomes rapid and small. The conjunctivæ become hyperæmic and the eyes have a staring appearance, the pupils being partially dilated and inactive to light. The complexion has a cherry red appearance. Froth may be present on the lips. The breathing is stertorous. The temperature is usually subnormal in the early stages of coma, but is sometimes raised in the later stages. There is relaxation of the sphincters in severe cases. Broncho pneumonia may develop if the coma is prolonged for more than a few hours. Occasionally prolonged asphyxia permanently damages the brain and the patient survives with paralysis, sensory loss, Parkinsonism or loss of memory. Such sequelæ are due, not to retention of carbon monoxide but to degeneration of nerve cells. The determining factor in their production is the length of time that the tissues have been subjected to oxygen lack. Old people or patients suffering from cardio vascular disease do not stand asphyxia as well as do robust persons.

Repeated daily exposure to small amounts of carbon monoxide occurs sometimes in garage mechanics, blast-furnace workers and cooks. They suffer no impairment of health, and they may develop true acclimatisation as indicated by compensatory polycythæmia—that is to say, an increase in the red cell count and hæmoglobin figure. Carbon monoxide is not a cumulative poison. In pure air, and with a sufficient volume of breathing, small amounts of this gas are readily ventilated out of the blood. There is therefore no such condition as chronic carbon monoxide poisoning.

Diagnosis—A simple test can be employed to prove the presence of carbon monoxide in the blood. A greatly diluted solution of the suspected sample is compared with that of normal blood similarly diluted. The latter is yellow, whereas blood containing even very small traces of carboxy-hæmoglobin is pink. When the proportion of carbon monoxide in the blood is more than 40 per cent of saturation, spectroscopic examination affords a confirmatory test.

Treatment—**PROPHYLACTIC**—The fact that his safety lamp continues to burn is no proof to the miner of the safety of air in which afterdamp may be present. He therefore carries a canary in a cage, for a bird shows signs of poisoning in a fraction of the time necessary in the case of a man. Hence, by watching the canary, timely warning may be obtained of the presence of enough carbon monoxide to endanger the life of the miner and his rescuer. A more convenient method for determining the concentration of carbon monoxide in the air is a portable direct-reading instrument sensitive to 10 p.p.m. of the gas. This employs a catalyst to promote oxidation of the gas, and the corresponding rise of temperature is indicated on a sensitive thermocouple. Carbon-monoxide recorders which operate continuously are installed in up-to-date vehicular tunnels.

In industry the structure of buildings must be regulated in such a way as to obviate unnecessary risk. Preventive measures must be strictly applied and a com-

petent person should be made responsible for inspecting the plant concerned at stated short intervals. He should see that there is no leakage and must keep a signed and dated record of such inspection. No person should be allowed to work single-handed in a place where exposure is to be anticipated, and a safe form of breathing apparatus must be worn. Activated charcoal does not effectively protect against carbon monoxide. Respirators must contain a mixture of 50 per cent. manganese dioxide, 30 per cent. copper oxide, 15 per cent. cobalt oxide and 5 per cent. silver oxide, known by the name *hopcalite*. This catalyses the oxidation of the carbon monoxide by the oxygen of the air. Iron and steel works must have first-aid men constantly on duty, trained to work as rescue squads and taught how to keep all apparatus in good order.

CURATIVE.—Warmth is essential in treatment. The patient should be wrapped in dry blankets and provided with hot-water bottles. Rest is absolutely necessary. The first and immediate consideration is the restoration of breathing, and the second the promotion of warmth and circulation. Work done in many countries since 1950 has shown that the Schafer method of artificial respiration gives inadequate ventilation in many subjects. It is now agreed that the arm-lift, back-pressure method of Holger Nielsen gives a higher uptake of oxygen than does the Schafer method and is easy to teach, accurate in performance and can be readily carried out over long periods. It has therefore been adopted by the International Red Cross and by all three of the Armed Services of Great Britain. All workers responsible for rescue work must understand that in resuscitation of persons who have ceased to breathe it is vitally important to apply artificial respiration *promptly*. Rescue men generally work in teams of three, each man working for 20 minutes and the team continuing for as long as 4 hours or until *rigor mortis* has obviously begun. The delay incident to the removal to a hospital may be fatal, and is justifiable only when there is no one at hand to give artificial respiration. If complications exist or arise which require hospital treatment, artificial respiration should be maintained in transit and after the arrival at the hospital until spontaneous respiration begins. For resuscitation of subjects exposed to carbon monoxide the use of a mixture of 95 per cent. oxygen and 5 per cent. carbon dioxide is of great value. It has been shown that the blood of men gassed with carbon monoxide up to 35 per cent. and to a 50 per cent. hæmoglobin saturation can be brought down to 15 per cent. saturation in 30 minutes when the oxygen-carbon-dioxide mixture is inhaled. The same men, gassed to comparable saturations, are relieved very slowly when oxygen alone is inhaled.

POISONING BY BARBITURATES

Acute barbiturate poisoning is rarely accidental and comes second to carbon monoxide as a cause of death by suicide. The barbiturates can be divided into four groups depending on their rapidity of action. The long-acting derivatives include barbitone (Veronal), phenobarbitone (Gardenal, Lumnal) and methyl phenobarbitone (Plumitone); barbiturates with intermediate action are allobarbitone (Dial), butobarbitone (Soneryl) and amylbarbitone (Amytal); and those with short action are cyclobarbitone (Phanodorm), pentobarbitone (Nembutal) and quinalbarbitone (Seconal). The ultra-short acting compounds used as anaesthetics are the soluble sodium salts of thiopentone (Pentothal), hexobarbitone (Evipan) and thialbarbitone (Kemithal). Sodium salts of the other derivatives are also obtainable for parenteral use. By far the most frequently encountered barbiturate in suicidal attempts is phenobarbitone.

Symptoms.—The history from witnesses is often unreliable and circumstantial evidence confusing. Thus unconsciousness may be attributed to injury due to a fall in the early stages of intoxication, or a patient in deep coma due to a barbiturate may be found in circumstances which suggest carbon monoxide poisoning. Diplopia, nystagmus, dysarthria and ataxia are constant in mild intoxication. In severe intoxication there is deep coma with subnormal temperature, raised pulse-rate, low blood

pressure, a variable but usually raised respiration rate with shallow and sometimes irregular breathing, small fixed pupils, absent reflexes, diminished deep reflexes and absent or flexor plantar responses. The pupils are normal in mild cases, constricted in severe intoxication and dilated and fixed when death is imminent, barbiturate poisoning is but an exaggerated form of surgical anaesthesia in which pupillary size and reaction can be related to depth of coma. The skin is usually cold and dry, cyanosis when present is peripheral in shock, or central in asphyxia. Fever is a sign of pneumonia, hyperpyrexia is of grave prognostic significance. Uncommon features include bullous skin lesions resembling burns, methaemoglobinæmia, hippus, strabismus, muscular rigidity and extensor plantar responses. Generalised convulsions or a state of mania rather than coma are unusual. Excitement and aggressive behaviour may occur during recovery from coma especially in epileptics.

Diagnosis—Other causes of prolonged coma, including head injury, cerebral vascular lesions, diabetes, hypoglycæmia and uræmia can usually be excluded without difficulty. In aspirin poisoning there is hyperpnoea with ketone bodies in the urine, alcohol is made apparent by its distinctive smell and cocaine produces wide dilatation of the pupils. Coma due to morphine however, may be indistinguishable from barbiturate poisoning. Laboratory aids to diagnosis include qualitative and quantitative estimations of barbiturates in the blood by ultra-violet spectrophotometry. Qualitative analysis is possible also by means of paper chromatography. For specimens with a relatively high concentration of barbiturate such as stomach content and urine, the estimation depends upon extraction and melting point determination or microcrystalline appearance.

Treatment—The early and effective treatment of anoxia and shock are of vital importance. Depth of coma may be increased by anoxia, and the establishment of a free airway may be followed by dramatic improvement. Where secretions have accumulated below the level of the glottis intermittent bronchoscopic suction is probably preferable to prolonged endotracheal intubation. Oxygen can be supplied by naso-pharyngeal catheter at a rate of 7 litres per minute. When shock is marked, warmth is essential and the foot of the bed should be raised. Turning the patient frequently to either side and the administration of penicillin will delay the onset of broncho-pneumonia, fluid loss should be replaced by means of intravenous therapy. Feeding by mouth should not be resumed too early because of the danger of the inhalation of vomit. Gastric aspiration and lavage are effective in removing unabsorbed barbiturates if performed within 4 hours of ingestion and colonic lavage may also be employed, but cerebrospinal fluid drainage is both useless and dangerous. Analeptics are of doubtful value in poisoning by the long acting derivatives, and if given in convulsive doses may increase the depth of coma. They may hasten the return of consciousness in poisoning due to the barbiturates with short action, and in milder cases dramatic awakening may occur. Picrotoxin is the most effective analeptic and is best given intravenously in 6 mg doses every 30 minutes. Large doses at more frequent intervals are sometimes tolerated but cumulation usually occurs if the intervals are less than 20 minutes.

Prognosis—The duration and depth of coma, the age of the patient and his general condition are factors which influence the immediate prognosis. Patients with Parkinsonism are particularly susceptible to the barbiturates, and alcohol is known to potentiate their effect. The prognosis is better in poisoning due to butobarbitone or allied compounds provided treatment is not delayed, paradoxically death may occur with smaller doses than are usually fatal in poisoning due to phenobarbitone or barbitone. Consciousness is retained when the level of phenobarbitone in the blood is below 5 mg per 100 ml, it may be retained when the level of barbitone in the blood is between 7 and 10 mg per 100 ml, but death may occur when the level of butobarbitone is between 2 and 3 mg per 100 ml. Where an underlying personality defect exists further suicidal attempts are not uncommon, but when the attempt is attributable

The subacute form of poisoning follows the taking of repeated doses of a soluble lead compound. It may occur from repeated medicinal doses of lead acetate given to control diarrhoea. Abdominal colic is pronounced, and constipation severe. The other symptoms of acute lead poisoning occur, but are less intense in character. A blue line usually appears in the gums. If the teeth are frequently cleaned it is less likely to be formed. If the symptoms are of long duration lead palsy may result.

Diagnosis—The diagnosis of acute or subacute lead poisoning can be confirmed by analysis of the vomit and faeces for lead during life, and after death by finding lead in the gastro intestinal tract, liver, spleen and kidneys. Acute and subacute lead poisoning are rarely fatal.

Treatment—If the patient is seen within 3 hours of swallowing the poison the stomach should be washed out with water. Intravenous injections of calcium versenate (calcium di sodium EDTA) must be given at once (see p. 371). The abdominal pain may be relieved by hot applications, repeated drinks of milk and large doses of calcium lactate 5 g (gr 75) three times a day. In severe colic by the slow intravenous injection of 15 ml of a 20 per cent solution of calcium glueonate, or of 10 ml of a 5 per cent solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. If necessary this treatment may be repeated in 2 hours. Should it not be available a hypodermic injection of gr $\frac{1}{16}$ atropine sulphate and gr $\frac{1}{4}$ morphine sulphate may be given. For some weeks saline aperients and a high calcium diet should be given. The diet should contain 3 pints of milk daily, including milk puddings, junket and ice cream, together with butter, cheese and eggs.

2 CHRONIC LEAD POISONING

Synonyms—Plumbism, Saturnism

Ætiology—Apart from a few cases arising from accidental causes, chronic lead poisoning is of occupational origin. Lead is now encountered in more than 200 industries. In Great Britain there are more than 1,500 workers in the lead industries and 150,000 painters. It has been known clinically for more than a hundred years that absorption of lead through the respiratory tract is very much more important than by the gastro intestinal tract, and this view has since been amply confirmed by experiments on cats. In the prevention of dust and fume great success has been secured from the application of the Factories Acts. Idiosyncrasy is a factor in the development of lead poisoning, certain persons being more susceptible than others. Alcoholism also seems to be a predisposing cause. The sources from which lead is derived in chronic poisoning are very numerous, and they may be divided into three groups.

1 **Occupational risks**—Men are exposed to danger in the smelting and tinning of metals, in vitreous enamelling, pottery glazing, shipbuilding, coach painting, plumbing and soldering, house painting, and in the manufacture of white lead, red lead, litharge, rubber, glass, cement, varnish, coloured pigments, linoleum and electric accumulators. Lead smelters are exposed to the fume and dust of furnaces and flues. Lead burners and chemical plumbers use oxy acetylene, oxy-hydrogen, or oxy coal gas blowpipes in their work. The very high temperature of such flames constitutes a much greater risk than that faced by the domestic plumber who uses a spirit blow-lamp. Painters are exposed when they rub down interior surfaces which have been painted with lead paint. The use of a blowlamp for burning off old paint is not without risk. A painter nowadays is very rarely exposed in mixing paint from the dry material, because it comes to him already mixed in oil. There is some risk to compositors who handle type metal, and to gasfitters who use red and white lead. It frequently happens that changes in methods or the appearance of new industries provide new causes of lead poisoning. Thus in ship breaking especially when warships are scrapped, the volatilisation of lead from the paint and red lead stopping on

the plating occurs in the heat of the oxy-acetylene blowpipe flames used for cutting purposes. In 1923 the great increase in the use of wireless receiving apparatus and motor-cars led temporarily to a greater number of cases of lead poisoning in electric accumulator factories. Sometimes the converse is true, and lead poisoning is found to show a remarkable diminution in a given industry. Thus, the substitution of machine methods for hand labour has abolished the disease among file cutters. The fall in the incidence of poisoning in coach painting is due to the enormous development of spray painting of motor-cars with leadless cellulose lacquers.

2. *Accidental causes.*—Drinking water, especially if it is soft, or contains traces of acid derived from peat or dead leaves, may dissolve lead from lead pipes or cisterns and so give rise to poisoning. Beer or cider drawn from casks through lead pipes may become heavily contaminated. Aerated waters delivered from syphons with pewter or lead valves may give rise to poisoning. The lead glaze on earthenware vessels may be dissolved by vinegar, lemon juice, cider or home-made wine. At one time the cooking of food in vessels tinned with a mixture of lead and tin gave rise to lead poisoning, especially if vegetable acids were present. The tinning of saucepans and food tins is carried out nowadays with pure tin. Tinned foods sometimes contain lead from solution of the solder used in the tinning process. The lead foil used for wrapping sweets or food may contaminate them. Cosmetics, hair-dyes and snuff weighted with litharge all have given rise to cases. Children with perverted appetites may chew the paint off their cots or toys. In Queensland, Australia, where the hot, dry climate causes flaking of painted surfaces, so that lead carbonate comes away as a white powder, children have been poisoned owing to nail-biting, thumb-sucking and the habit of licking the raindrops off the painted balconies, railings, fences and roofs of wooden houses.

3. *Abortifacient uses of lead.*—Lead attacks the chorion epithelium, causing abortion in pregnant women. A like effect has been observed in animals in the proximity of lead works. Lead oleate plaster, known as diachylon, has been used in certain districts by pregnant women in order to cause miscarriage, the substance being swallowed in small portions rolled up in the form of a pill. To do this is very dangerous, for if miscarriage comes about, death occurs later from lead poisoning. In consequence the sale of lead oleate has been restricted by placing it in Part I of the Poisons Schedule.

Pathology.—In chronic poisoning lead is stored in the skeleton, and under certain circumstances is released to attack (i) muscle, causing abdominal colic and lead palsy; (ii) the reticulated red cell, causing punctate basophilia (stippling) and anaemia; (iii) the chorion epithelium, causing abortion and (iv) the brain, causing encephalopathy.

In 1925 Fairhall studied the physico-chemical behaviour of lead in the animal body. It is probably transported in the blood plasma as the insoluble tertiary phosphate in the highly dispersed or colloidal form. At different stages of intoxication its distribution within the body varies somewhat. When absorption is slow it migrates to the skeleton, where about 95 per cent. is held without harm during the chronic stage of plumbism. If, however, large quantities of lead are being absorbed or are being liberated from the bones, lead is distributed throughout the tissues and the percentage in the bones is reduced. Under these conditions acute symptoms of poisoning occur. It has been shown that the total amount of lead stored in the skeleton in lead workers varies from 0.2 to 0.8 g. This deposition of lead suggests a mechanism similar to that involved in the deposition of calcium phosphate. Repeated observations by Aub and Fairhall showed that conditions which favour storage of calcium in the body also favour storage of lead. When conditions are unfavourable for the retention of calcium the excretion of stored lead increases.

In studies of lead excretion it is to be noted that normal persons with no occupational exposure to lead may excrete lead in the faeces and urine. This happens because

lead is frequently present in the soil, and hence in vegetation and animal food. In normal persons the concentrations of lead may be 0.03 mg. per 100 g. of blood, 0.027 mg. per litre of urine and 0.28 mg. per 24 hours' sample of faeces. In toxicological analysis no satisfactory figures can be obtained unless specimens of stool and urine are collected for at least 3 days. A man working in a dusty lead industry, in addition to inhaling lead, may swallow repeated small amounts and pass lead unabsorbed in the faeces. The only proof of absorption, therefore, is to find lead in the urine. If specimens be taken some weeks after removal from exposure, the output may reach about 1 mg. for each 24 hours in the faeces and about 0.3 mg. in the urine. Under effective treatment the faecal excretion may rise to about 2 mg. in each 24 hours. It should be emphasised that the presence of lead in the excreta is not necessarily proof that a lead worker is suffering from lead poisoning. Many such workers are insusceptible and have never suffered from any of the toxic episodes.

Lead palsy begins in the muscles, and fatigue determines the site of paralysis. The chemical explanation offered is that in regions of muscular activity the excess lactic acid which diffuses from the fatigued muscle cells combines with the lead phosphate in the blood to form lead lactate. As this soluble lactate comes into contact with inorganic phosphate at the surface of the muscle cells the lead is re-precipitated as insoluble phosphate, causing alterations in the surface permeability.

the patient himself. Often a man's occupation does not at first sight suggest that he is exposed to compounds of lead. A man describing himself as a fitter may be exposed to dust or fume of lead, this fact is only elicited in answer to a leading question. The occupation of a cooper becomes dangerous when the barrels worked upon have contained compounds of lead. Vitreous enamellers working, for example, on baths, sift a powder containing lead silicate on to the bath which has been heated in a furnace. They sometimes use a compressed-air apparatus which forces the enamel through a sieve. In the electric accumulator trade pasters fill the spaces in accumulator plates with a paste containing litharge and red lead. Colour manufacturers grind colours into a fine powder under edge runners with the necessary production of much dust. Amongst other things they grind lead chromate and red lead. A slate mason may construct storage tanks by fixing together slabs of slate with materials containing oxides of lead. A bullion refiner may use a process in which he adds lead to refinable silver in a furnace and taps off molten litharge. A rubber compounder adds oxides of lead to crude rubber in preparation for vulcanisation. A girl describing herself as a perambulator maker may be employed painting the body work of perambulators and then rubbing down the surface with dry sand-paper. An embroidery worker sometimes stencils materials by dabbing on the pattern commercial white lead instead of chalk.

Symptoms—The toxic episodes resulting from the absorption of lead are colic, palsy, anæmia and encephalopathy. The blue line on the gums is a sign of absorption and not of intoxication.

Lead colic—This is the most common and dramatic of the acute manifestations of plumbism. It is ten times as common as lead palsy. An attack of colic is preceded by several days of constipation. The pain is of a tearing or gripping nature and of variable intensity. It is situated around or below the umbilicus, and the patient often indicates where it is by spreading both hands widely over the abdomen. While suffering from colic the patient is cold, pale and often drenched with perspiration. He commonly bends over and may writh about the bed in intense pain. Examination shows a scaphoid abdomen, held tense, but showing no rigidity. Vomiting frequently occurs at the onset of the pain.

Lead palsy—This does not belong to the category of polyneuritis, either clinically or pathologically. It is in the first instance a muscle disease. Fatigue plays a most important part in determining the sites attacked. Where the muscle palsy is neglected the lead attacks the motor nerve fibres and ultimately the anterior horn cells of the spinal cord (see also p. 1593). Paralysis does not appear to be closely related to length of exposure. It may develop during the first months of work, or only after many years' exposure. The commonest form is the well-known wrist-drop which begins usually in the right hand and later becomes bilateral. The palsy first appears in the long extensors of the middle and ring fingers. It spreads to the other fingers, and then to the long extensors of the wrists. The supinator longus (brachioradialis), and usually the long abductor of the thumb escape. The brachial type of paralysis involves the deltoid, biceps and supinator longus, but it is very rare for this to occur without wrist drop. A third form of lead palsy to which progressive atrophy occurs of the thenar and hypothenar eminences, together with the interossei, used to be common in the left hand of file-cutters. In view of the theory that fatigue plays an important part in determining the site of lead paralysis, this observation is of great interest, for in their work file cutters not only used particularly the muscles mentioned but placed the greatest strain upon the left hand. The substitution of machine methods for hand labour has abolished lead poisoning amongst file makers. Lead palsy rarely occurs in the lower limbs, but when it does so it affects the extensors of the toes, giving rise to foot drop.

Anæmia—Secondary anæmia with basophil punctation (stippling) of the red cells is characteristic. It is usually mild, and it is rare to find less than 3 million red

cells per c mm Because of the loss of circulating red cells there is compensatory regeneration of erythrocytes, with a high reticulocyte count

Encephalopathy—Most of the ancient writers speak of the frequent occurrence of convulsions in lead poisoning, but fortunately with the improvement of industrial conditions the incidence of lead encephalopathy has progressively decreased until to day cases are rarely seen It is the most dramatic manifestation of lead poisoning, and is always of serious prognostic significance In severe cases of plumbism the patient is dull, with poor memory and inability to concentrate The onset of encephalopathy is nevertheless sudden, usually with epileptiform convulsions It may be divided into three groups—convulsive, comatose and delirious The lymphocyte count in the cerebrospinal fluid may reach 100 per c mm

The lead line—The lead line consists of fine granules of pigment arranged in the form of a dark blue stippled line within the tissues of the gum about a millimetre from the border of the teeth It is more marked round infected or dirty teeth, and is occasionally found on the mucosa of the cheek opposite such teeth Despite the pigment lying within the tissues, careful cleansing of the mouth and teeth often causes it to disappear Its clinical significance should be clearly recognised It is an indication of absorption and not of intoxication Its intensity and size provide a rough guide to the duration and severity of exposure to lead

Coproporphyrinuria—In chronic plumbism the urine contains large amounts of coproporphyrin III This is probably newly formed as the result of the action of lead and is not a product of hæmoglobin breakdown Although coproporphyrinuria is found in conditions other than lead poisoning, it is much more marked in plumbism than in other disorders and is often found before basophilic stippling is demonstrable

Chronic nephritis—In Queensland in 1933 Nye studied a series of 34 patients with nephritis who had suffered from lead palsy in childhood Inquiry showed that they had all spent their childhood in wooden houses, 30 were nail biters or thumb-suckers, all but 7 had albuminuria and 29 had well established renal insufficiency Some had renal dwarfism, hypertension, marked urea retention and low urinary concentration The death rate was correspondingly high In adults it seems that ischaemic nephritis may occur after prolonged exposure to lead dust or fume but that it is unusual

Diagnosis.—Opinions differ widely as to what is necessary for the diagnosis of lead poisoning Constipation and slight stippling of red cells are insufficient, neither a blue line on the gums nor detection of lead in the urine can be taken as proof of poisoning, for the patient may be insusceptible Where a worker is exposed to risk, a diagnosis of lead poisoning can be made before the occurrence of a toxic crisis A falling hæmoglobin percentage, with or without a rising punctate basophile count, raises a suspicion that absorption is passing into poisoning The suspicion becomes a certainty when these changes are marked or progressive The urine should be collected for at least 3 days and examined for lead There is a danger of wrongly attributing to lead poisoning any symptoms which may occur in persons exposed to lead Acute appendicitis, chronic gastric or duodenal ulcer, and carcinoma of the stomach occur in lead workers as they do in others They must be carefully differentiated from colic Equally a lead worker can suffer from pernicious anaemia or secondary anaemia due to piles, melæna or hæmatemesis It is important to remember that lead poisoning has to be severe before the red cell count drops below 3 million In industrial cases the blue line is unlikely to give rise to confusion A similar phenomenon is commonly seen in patients under treatment with bismuth preparations given intramuscularly The differential diagnosis of lead palsy should give rise to no difficulty, especially as the changes are entirely motor In a case of peripheral neuritis in which there are motor, sensory and pigmentary changes, the possibility of arsenic poisoning must be considered Litigation hysteria is all too common

in the lead worker. The manifestations include hysterical spasm of the hand and arm, weakness of various movements, including the flexors of the wrists and fingers, glove and stocking anæsthesia, complete hemi anæsthesia and hysterical aphonia. Such symptoms are rarely alleviated until legal proceedings are completed.

Treatment—**PROPHYLACTIC**—The treatment of chronic lead poisoning is essentially preventive. Food and drink containing organic acids should not be stored in earthenware vessels glazed with lead. Supplies of soft water for drinking purposes when delivered through lead pipes should be artificially hardened by the addition of calcium salts. Lead pipes used to convey beer or cider from the cellar to the bar engine in public houses must be lined with tin. Children's toys and cots must never be painted with lead paint. The law must restrict the sale of lead oleate and forbid the addition of litharge to snuff in order to make it heavy.

In industry less than 60 cases of lead poisoning were notified in 1950 as compared with more than 1250 in 1889. In Great Britain preventive measures are carried out with such success that the majority of cases of lead poisoning are mild. It is unusual to day to meet with a case either of severe colic or of extensive palsy, and encephalopathy has been abolished. The most important single measure of prophylaxis is the prevention of dust and fume. In achieving this, great success has been secured from the application of the principle upon which Sir Thomas Legge always laid so much stress, namely, to apply methods entirely external to the workman—methods over which he himself can exercise no control. One such method is exhaust ventilation applied through hoods at the point of origin of dust or fume. Benches, tools, floors and walls must be spotless, often at the expense of the constant vigilance of several good foremen. No scrap lead nor dry white lead should be handles unless it has been thoroughly soaked with water from a hose. As far as possible mechanical means, such as cranes, rails, hoists, covered conveyers and hoppers, and automatic packing machinery must be substituted for hand carriage.

Fortunately about 50 per cent of the white lead manufactured in Great Britain is never handled in the dry state. It is made by the Euston process in which lead acetate is treated with carbon dioxide, giving results much more quickly than was possible with the old Dutch stack process. The plant is completely enclosed so that the white lead is not seen from the time the pig lead enters the process until it appears as the finished product, namely ground white lead in linseed oil. Since a white lead worker may handle in the course of a day at least as much white lead as a painter handles in a year, the value of this enclosed method will at once be realised. In the manufacture of litharge and red lead it is impracticable to use wet methods and it is therefore necessary to use machinery designed to minimise dust. Since 1937 it has been illegal for a painter to rub down by dry methods any indoor structure previously treated with lead paint. Dust can be avoided by using a damp rubbing down process for lead painted surfaces. Waxed sandpaper which the workman dips repeatedly in a bucket of water has made this possible.

In addition to cleanliness in the workplaces, personal cleanliness is of the first importance. Cloak rooms, washing rooms, mess rooms, baths, nail brushes, towels and soap must be provided. The hands should always be washed before eating and the work people urged to take a warm bath frequently. The bringing of food or drinks into the work-rooms should be forbidden, and so also should smoking at work. Medical examination of the workers exposed must be carried out periodically. At present there is no biological test by which to select workmen immune to the toxic effects of lead. Since they have been found unduly susceptible it is necessary to forbid the employment of pregnant women and of all persons under 18 years of age in the potteries and other lead trades.

Any worker who develops one of the toxic effects of lead must be suspended from work without financial hardship for 3 months. At the end of this time only if it has been possible to modify the operation or condition of work, including hours, which

cells per c.mm. Because of the loss of circulating red cells there is compensatory regeneration of erythrocytes, with a high reticulocyte count.

Encephalopathy.—Most of the ancient writers speak of the frequent occurrence of convulsions in lead poisoning, but fortunately with the improvement of industrial conditions the incidence of lead encephalopathy has progressively decreased until to-day cases are rarely seen. It is the most dramatic manifestation of lead poisoning, and is always of serious prognostic significance. In severe cases of plumbism the patient is dull, with poor memory and inability to concentrate. The onset of encephalopathy is nevertheless sudden, usually with epileptiform convulsions. It may be divided into three groups—convulsive, comatose and delirious. The lymphocyte count in the cerebrospinal fluid may reach 100 per c.mm.

The lead line.—The lead line consists of fine granules of pigment arranged in the form of a dark blue stippled line within the tissues of the gum about a millimetre from the border of the teeth. It is more marked round infected or dirty teeth, and is occasionally found on the mucosa of the cheek opposite such teeth. Despite the pigment lying within the tissues, careful cleansing of the mouth and teeth often causes it to disappear. Its clinical significance should be clearly recognised. It is an indication of absorption and not of intoxication. Its intensity and size provide a rough guide to the duration and severity of exposure to lead.

Coproporphyrinuria.—In chronic plumbism the urine contains large amounts of coproporphyrin III. This is probably newly formed as the result of the action of lead and is not a product of hæmoglobin breakdown. Although coproporphyrinuria is found in conditions other than lead poisoning, it is much more marked in plumbism than in other disorders and is often found before basophilic stippling is demonstrable.

Chronic nephritis.—In Queensland in 1933 Nye studied a series of 34 patients with nephritis who had suffered from lead palsy in childhood. Inquiry showed that they had all spent their childhood in wooden houses; 30 were nail-biters or thumb-suckers, all but 7 had albuminuria and 29 had well-established renal insufficiency. Some had renal dwarfism, hypertension, marked urea retention and low urinary concentration. The death-rate was correspondingly high. In adults it seems that ischæmic nephritis may occur after prolonged exposure to lead dust or fume but that it is unusual.

Diagnosis.—Opinions differ widely as to what is necessary for the diagnosis of lead poisoning. Constipation and slight stippling of red cells are insufficient; neither a blue line on the gums nor detection of lead in the urine can be taken as proof of poisoning, for the patient may be insusceptible. Where a worker is exposed to risk, a diagnosis of lead poisoning can be made before the occurrence of a toxic crisis. A falling hæmoglobin percentage, with or without a rising punctate basophile count, raises a suspicion that absorption is passing into poisoning. The suspicion becomes a certainty when these changes are marked or progressive. The urine should be collected for at least 3 days and examined for lead. There is a danger of wrongly attributing to lead poisoning any symptoms which may occur in persons exposed to lead. Acute appendicitis, chronic gastric or duodenal ulcer, and carcinoma of the stomach occur in lead workers as they do in others. They must be carefully differentiated from colic. Equally a lead worker can suffer from pernicious anaemia or secondary anaemia due to piles, melæna or hæmatemesis. It is important to remember that lead poisoning has to be severe before the red cell count drops below 3 million. In industrial cases the blue line is unlikely to give rise to confusion. A similar phenomenon is commonly seen in patients under treatment with bismuth preparations given intramuscularly. The differential diagnosis of lead palsy should give rise to no difficulty, especially as the changes are entirely motor. In a case of peripheral neuritis in which there are motor, sensory and pigmentary changes, the possibility of arsenic poisoning must be considered. Litigation hysteria is all too common

in the lead worker. The manifestations include hysterical spasm of the hand and arm, weakness of various movements, including the flexors of the wrists and fingers, glove and stocking anæsthesia, complete hemi-anæsthesia and hysterical aphonia. Such symptoms are rarely alleviated until legal proceedings are completed.

Treatment.—**PROPHYLACTIC.**—The treatment of chronic lead poisoning is essentially preventive. Food and drink containing organic acids should not be stored in earthenware vessels glazed with lead. Supplies of soft water for drinking purposes when delivered through lead pipes should be artificially hardened by the addition of calcium salts. Lead pipes used to convey beer or cider from the cellar to the bar engine in public houses must be lined with tin. Children's toys and cots must never be painted with lead paint. The law must restrict the sale of lead oleate and forbid the addition of litharge to snuff in order to make it heavy.

In industry less than 60 cases of lead poisoning were notified in 1950 as compared with more than 1250 in 1889. In Great Britain preventive measures are carried out with such success that the majority of cases of lead poisoning are mild. It is unusual to-day to meet with a case either of severe colic or of extensive palsy, and encephalopathy has been abolished. The most important single measure of prophylaxis is the prevention of dust and fume. In achieving this, great success has been secured from the application of the principle upon which Sir Thomas Legge always laid so much stress, namely, to apply methods entirely external to the workman—methods over which he himself can exercise no control. One such method is exhaust ventilation applied through hoods at the point of origin of dust or fume. Benches, tools, floors and walls must be spotless, often at the expense of the constant vigilance of several good foremen. No scrap lead nor dry white lead should be handles unless it has been thoroughly soaked with water from a hose. As far as possible mechanical means, such as cranes, rails, hoists, covered conveyers and hoppers, and automatic packing machinery must be substituted for hand carriage.

Fortunately about 50 per cent of the white lead manufactured in Great Britain is never handled in the dry state. It is made by the Euston process in which lead acetate is treated with carbon dioxide, giving results much more quickly than was possible with the old Dutch stack process. The plant is completely enclosed so that the white lead is not seen from the time the pig lead enters the process until it appears as the finished product, namely ground white lead in linseed oil. Since a white lead worker may handle in the course of a day at least as much white lead as a painter handles in a year, the value of this enclosed method will at once be realised. In the manufacture of litharge and red lead it is impracticable to use wet methods, and it is therefore necessary to use machinery designed to minimise dust. Since 1937 it has been illegal for a painter to rub down by dry methods any indoor structure previously treated with lead paint. Dust can be avoided by using a damp rubbing down process for lead painted surfaces. Waxed sandpaper which the workman dips repeatedly in a bucket of water has made this possible.

In addition to cleanliness in the workplaces, personal cleanliness is of the first importance. Cloak-rooms, washing-rooms, mess-rooms, baths, nail-brushes, towels and soap must be provided. The hands should always be washed before eating and the work-people urged to take a warm bath frequently. The bringing of food or drinks into the work-rooms should be forbidden, and so also should smoking at work. Medical examination of the workers exposed must be carried out periodically. At present there is no biological test by which to select workmen immune to the toxic effects of lead. Since they have been found unduly susceptible, it is necessary to forbid the employment of pregnant women and of all persons under 18 years of age in the potteries and other lead trades.

Any worker who develops one of the toxic effects of lead must be suspended from work without financial hardship for 3 months. At the end of this time only if it has been possible to modify the operation or condition of work, including hours, which

were responsible for the trouble may he be allowed to return to his job. By patient insistence the works' doctor must teach the men their own responsibilities in the safety programme. The co-operation of the workmen will be forthcoming if the approach be the right one, the responsibility for procuring it lies with the doctor.

In the prevention of lead poisoning a diet of high calcium content plays its part. In lead works in Great Britain it has for many years been customary to provide the workmen free of cost with a glass of milk each morning. This is empirical treatment of considerable merit, anticipating as it did by many years the discovery that a high calcium intake assists the storage of lead in a harmless form in the bones. Workers should, in addition, take aperients regularly.

CURATIVE.—Treatment which aims at the cure or amelioration of lead poisoning should never be made the excuse for negligence in enforcing all the known measures for the prevention of exposure and absorption. Aub and his collaborators showed in 1925 that a high calcium intake causes lead excretion rapidly to diminish. It follows that a high calcium diet is useful in treatment. In mild cases of lead poisoning a diet containing 2 pints of milk a day or a daily dose of 10 g. of calcium lactate is all that is necessary to store lead in the bones so that it will not be free in the circulation to cause harm. In cases of lead poisoning showing toxic symptoms the diet should contain 3 pints of milk daily and include milk puddings, junket and ice cream together with butter, cheese and eggs. Large quantities of calcium lactate 5 g. (gr 75) three times a day, should be given. In the presence of acute symptoms no attempt should be made to increase the elimination of lead, so much is already circulating that it is safer to encourage further storage.

Methods used to increase the excretion of lead—The ideal method to increase the excretion of lead from the tissues is still being sought. In more than a hundred years many nations have contributed to this problem. In 1844 France gave us potassium iodide, then the United States of America gave us first the use of acid salts with a low calcium diet (1925) and then sodium citrate (1943) and finally Switzerland gave us the use of versene compounds (1948).

(i) *Potassium iodide*—Potassium iodide was first used in the treatment of lead poisoning in 1844. The dose should be increased from gr 5 three times a day to gr 15 three times a day. Its physiological effectiveness appears to diminish progressively after the first few days of treatment. It has been known to precipitate an acute attack of lead poisoning in an apparently healthy subject as long as 16 years after exposure to lead has ceased.

(ii) *Ammonium chloride with a low calcium diet*—A few weeks after the acute toxic episodes have passed, the elimination of lead may be accelerated by the use of a low calcium diet, together with ammonium chloride to facilitate the release of lead from the bones. All milk, milk products, green vegetables and eggs are omitted from the diet, which may, however, contain meat, liver, chicken, potato, peas, rice, tomato, banana, apple, lemon, tea, coffee, sugar, honey, salt and pepper. In those places where the water supply is hard, vegetables should be cooked in distilled water and all drinks made up with it. Ammonium chloride is administered cautiously in doses of 1 g. (gr 15) given in a glass of water eight or ten times daily for 3 weeks at a time. The dose should be reduced if loss of appetite and headache appear, for these symptoms indicate the limit of tolerance to such treatment. Since it would doubtless require several years it is useless to attempt the elimination of all the lead stored in the body. It is desirable to eliminate only the most readily mobilised lead. Thus, after 3 weeks treatment by a low calcium diet and ammonium chloride there should be a rest period of a week with normal diet and abundance of milk to correct the calcium deficiency. Treatment to accelerate elimination should then begin again. Neither ammonium chloride nor potassium iodide should be used in the presence of nephritis or of toxic symptoms. Should any toxic episode appear during the use of ammonium

chloride or potassium iodide, these drugs must be stopped and a high calcium diet at once used to favour the storage of lead

(iii) *Sodium citrate*—Because all previous methods used to eliminate lead from the body involved the risk of making the symptoms worse, attempts were made to render the mobilised lead harmless by converting it into a more complex chemical substance. Since in dilute solutions sodium citrate dissolves tertiary lead phosphate, and since the soluble complex of lead citrate so formed has an extremely low dissociation constant it was suggested that this might prove to be a safe and effective way to rid the body of lead. Favourable results from treatment by sodium citrate were reported but better methods have since been devised

(iv) *Calcium di-sodium versenate*—In 1948 it was shown that sodium ethylenediamine tetra-acetate (sodium E D T A, sodium versenate) is a powerful chelating agent having a strong affinity for calcium and heavy metals. This property has been utilised in the treatment of acute and chronic lead poisoning. When calcium di-sodium E D T A (calcium E D T A, calcium versenate) is administered parenterally the lead displaces the calcium and the resulting lead chelate is excreted by the kidney. Not only is the rate of excretion of the metal thus increased, but the circulating un-ionised chelate is much less toxic than would be a similar quantity of ionised metal. Four to eight daily intravenous injections of 3 g. of calcium E D T A in 600 ml. of 5 per cent dextrose in distilled water are given over a 2-hour period. Striking increases in the urinary excretion of lead as high as 13 mg. per day occur, and the urinary coproporphyrin level falls. Excessive dosage must be avoided. Calcium E D T A may be lethal in animals. Patients treated with large doses of sodium E D T A have died from renal tubular necrosis.

Treatment of colic—Treatment with a high calcium diet almost invariably brings relief within 2 days. The relief of lead colic by calcium therapy involves more than the ability of calcium to favour storage of lead. Since the pain is due to violent peristalsis behind a contracted tonic ring of intestine, the antispasmodic effect of calcium salts on involuntary muscle is beneficial. In severe cases it is possible, by the slow intravenous injection of 15 ml. of a 20 per cent solution of calcium gluconate, or of 10 ml. of a 5 per cent solution of calcium chloride, to relieve the pain by the time the injection is over. The patient feels hot and flushed and may vomit. If necessary, the injection may be repeated in 2 hours. Should such treatment not be available, a hypodermic injection of atropine sulphate gr $\frac{1}{16}$ may be given. Enemata of olive oil and mild aperients may be used.

Treatment of palsy—During the development of lead palsy a high calcium diet should be used to favour the storage of lead. Massage and electrical treatment are also useful. In the early stages the hands, when affected by wrist drop, should be supported on splints.

Treatment of encephalopathy—Lead encephalopathy should be treated by lumbar puncture and a high calcium diet. Of 6 cases observed in the United States of America, 3 occurred before this treatment was in use and all died. The other 3 were given large quantities of milk and calcium lactate and promptly recovered. The control of encephalopathy by the use of calcium E D T A in children who had ingested lead paint from toys shows promising results (1954).

3 TETRA-ETHYL LEAD POISONING

Ætiology.—Tetra-ethyl lead is an organic, lipid-soluble compound readily absorbed through the skin and respiratory tract. It is a clear, heavy, oily liquid with a peculiar sweetish odour, and is somewhat volatile at ordinary temperatures. It is added to petrol in proportions up to 1 in 1260 as an antidetonant. Twelve per cent of the annual consumption of refined lead is used in its manufacture. In 1923, when it was first manufactured in the United States of America, 149 cases of encephalo-

pathy occurred in men employed on three separate plants. Within 17 months 11 deaths were reported. Much excitement and alarm were caused and this led at first to the prohibition of the manufacture. In the War of 1939-1945 a new hazard arose in the process of cleaning storage tanks which had held ethyl petrol. In England some of these tanks were underground and were of 4000 tons capacity. Twenty five cases of poisoning by tetra ethyl lead occurred, 2 of them fatal. War conditions in countries of the Middle East and Far East made the cleaning of tanks difficult to supervise, and there were 200 cases of poisoning with 40 deaths.

Symptoms—The early symptoms include insomnia, loss of weight, anorexia and morning nausea but there is no colic. Mental manifestations dominate the clinical picture, and in severe cases restlessness, bad dreams, hallucinations and delusions are common. Several symptom complexes have been distinguished—the delirious, manic, confused and schizophrenic. Weakness, tremor, muscular pains and ease of fatigue are frequent complaints. The tremors affect the extremities, lips and tongue, and are coarse and jerky, and aggravated both by effort and by attempts at control. With severe exposure there may be the abrupt onset of acute maniacal symptoms with suicidal tendencies or the occurrence of a convulsion. Less severe cases begin with insomnia, sleep being difficult, broken and restless, sometimes with wild and terrifying dreams. By day, mental excitement may be marked, headache is usual and often severe and vertigo is frequent. Blurred vision and diplopia owing to weakness of the extrinsic ocular muscles are occasional complaints. Evidences of meningeal irritation are absent, the cerebrospinal fluid may at times be under increased pressure, but it is not otherwise abnormal. Punctate basophilia is absent or slight. In the patients who recover, all symptoms disappear in from 6 to 10 weeks. Occasionally an anxiety state persists for a time.

Treatment—(a) **SYMPTOMATIC**—The sedative action of repeated doses of barbiturates together with adequate fluid intake are the essentials in treatment. Morphine is contra indicated. Glucose 5 per cent in saline may be given intravenously up to 3 litres a day, and if it is given as a drip, hexobarbitone may be added. In severe cases from 2 to 4 g. of magnesium sulphate in 2 per cent aqueous solution should be given intravenously accompanied by doses of pentobarbitone sodium up to gr 15 daily by mouth. Enemata of 6 oz. of a saturated solution of magnesium sulphate often have a sedative effect when they can be retained.

(b) **PREVENTIVE**—By meticulous attention to detail it is possible to manufacture tetra ethyl lead and to blend it with petrol without risk to the workers. Both manufacture and blending are carried out in closed systems. Elaborate precautions are taken in transport, storage and handling of the fluid, and great care is exercised to avoid leakage or spilling. In blending and laboratory work impervious gloves and respirators are used. Strict regulations must be laid down for the cleaning of tanks which have contained leaded petrol. Those responsible should make it quite clear that such work is never to begin without reference to some authorised person. This makes it possible to do the work under supervision and to use trained workmen properly equipped with protective clothing. Although ethyl petrol contains less than one part in a thousand of tetra ethyl lead it should not be used for cleansing the skin nor for dry cleaning and to prevent this it is coloured by a dye. While decarbonising engines which have burned leaded petrols mechanics must wear dust masks. Routine medical examinations of workmen and technicians should be carried out wherever possible.

ARSENICAL POISONING

Arsenic is the most important of the irritant poisons, and owing to the almost tasteless property of many of its compounds and preparations it is one of the commonest poisons used for homicidal purposes. At one time it had a reputation as a

cosmetic, and was added to face powders and skin lotions. It is practically never used now for such purposes.

Occurrence.—*White arsenic*, arsenious acid, or arsenious anhydride, As_2O_3 , is the most important of the compounds of arsenic. It occurs in the form of a white powder, or in lumps like glass or porcelain *vitreous arsenic*. The powdered form resembles powdered sugar or flour, and when mixed with food is tasteless. It is slightly soluble in cold water, an ounce of cold water dissolving from gr $\frac{1}{2}$ to 1. In boiling water it is twelve times more soluble, from gr 6 to 12 dissolving in an ounce. Alkaline solutions readily dissolve arsenic. If white arsenic is sold to the public the law requires that it should be mixed with soot or indigo to colour it. It is used in the composition of sheep dip, arsenical soap and rat poison.

Metallic arsenic is a black powder. It is very poisonous, and is used for killing flies. *Copper arsenite* (Scheele's green) is bright green in colour, and used to be employed for colouring wall-paper, toys, floorcloths and fabrics. Its use for such purposes has fortunately been abolished. *Arsenious sulphide*, or orpiment, is a yellow powder known as king's yellow. *Arsenic acid*, in the form of its potassium and sodium salts, which are white, crystalline and soluble in water, is used as a fly poison. *Sodium arsenite*, in the form of solutions of arsenic in caustic soda, or in sodium carbonate, is commonly used for the preparation of fly-papers, weed killer, preservative for wood and arsenical sprays for fruit trees. Some of these preparations contain from 20 to 40 per cent of arsenic in solution, and are intensely poisonous.

Arsenic in food.—Accidental contamination of food with arsenic, or its preparations, such as weed-killer, has occurred. Arsenical pigments have been used for colouring sweets and cakes, with fatal result. A serious outbreak occurred in 1900, owing to the contamination of commercial glucose by arsenic. Sulphuric acid prepared from pyrites and containing a considerable amount of arsenic had been used in the process of the conversion of starch into commercial glucose, so that the latter became impregnated with arsenic. The use of the glucose in the manufacture of beer led to the outbreak of arsenical beer poisoning which occurred in Manchester. A Royal Commission investigated the cause of this epidemic, and made safeguards against the further occurrence of such poisoning. Limits of the amount of arsenic permitted in food stuffs were fixed at $\frac{1}{100}$ gr per gallon for liquids and per pound for solids.

Arseniuretted hydrogen, or *arsine*, is a poisonous gas occurring as a by product in industry. *Dimethylarsine* is a poisonous gas produced by the action of moulds upon certain compounds of arsenic. Other *aliphatic arsines* and also *aromatic* and *heterocyclic arsines* have been handled in studies directed to chemical warfare. The *arsenobenzene* derivatives which are used in the treatment of syphilis and other diseases, may give rise to poisoning.

Pathology.—Arsenic compounds poison the enzyme system responsible for the oxidation of pyruvic acid in the intermediary metabolism of carbohydrates in tissue cells. It is known that the pyruvate oxidase system contains a component sensitive to very small concentrations of arsenite. In 1909 Ehrlich showed that arsenic compounds had a strong affinity for sulphhydryl groups, and his work led to the observation that when such substances combined with tissue proteins the active sulphhydryl group of the latter spontaneously disappeared. In 1943 Peters showed that when Lewisite reacted with keratin, approximately 75 per cent of the bound arsenic was in combination with two thiol groups. He then found that simple 1, 2-dithiols are capable both of exerting an antidotal action against the poisoning of the pyruvate oxidase system by trivalent arsenic compounds and of reversing this poisoning when once established. This work was the origin of dimercaprol (B A L, British Anti Lewisite).

Varieties.—The varieties of arsenical poisoning are—(1) acute, (2) chronic, (3) arseniuretted hydrogen poisoning, (4) poisoning by organic arsines and (5) poisoning by arsenobenzene derivatives (see p 229).

1 ACUTE ARSENICAL POISONING

Pathology—The stomach contents usually contain much mucus, which may be blood stained. The signs of gastro intestinal inflammation are present. The mucous membrane is swollen, red and congested, and petechiæ are usually well marked. The redness is most marked on the summits of the rugæ. When the arsenic has been taken in solid form, white or pigmented particles may be seen on the mucous membrane of the stomach. The duodenum is red and congested, and petechiæ may be present, there is usually marked yellow staining, due to altered bile. The small intestine may show similar signs to the duodenum, but these diminish on passing downwards. The liver, kidney and other organs may show cloudy swelling. In fatal cases the arsenic absorbed into the tissues has a preservative action, and tends to delay putrefaction.

Symptoms—When the poison is taken by the mouth, if diluted well or mixed with food, no taste or pain in the mouth or throat is experienced. The symptoms begin within an hour if the stomach is empty, but may be delayed if the stomach is full, and if the poison is in the solid state there will be further delay. A burning pain occurs in the epigastric region, and nausea and vomiting usually follow. The vomit will contain any food present in the stomach, and there is often much mucus. Bile is usually present, and sometimes streaks of blood. As the poison is passed on to the intestine, abdominal pain, of a griping or colicky type, and usually diarrhœa occur. The stools are watery, and may contain flakes of mucus. The continued vomiting and diarrhœa cause exhaustion, faintness and collapse. Cramps in the legs may occur, but are not a constant symptom. In a severe case restlessness, stupor and coma develop, and death follows shortly. Death in an acute case may occur within 24 hours, or may be delayed for 3 days or more. When several repeated doses are taken, so that the symptoms are protracted over several days, some of the symptoms of chronic arsenical poisoning may develop.

Fatal dose—Grains 2 of arsenic have caused death in an adult, and this is accepted as a possible fatal dose.

Treatment—The stomach should be washed out by copious lavage. In severe cases injections of 3 mg. of dimercaprol (B.A.L.) per kilogram of body-weight (200 mg. for an average adult) should be given every 4 hours for the first 2 days, followed by less frequent injections for 10 days. This treatment may give rise to nausea, vomiting, salivation, lacrimation and feelings of burning and constriction in the throat and chest. Pain is relieved by the hypodermic injection of morphine. Demulcent drinks such as olive oil, liquid paraffin, kaolin or egg albumen should be given.

2 CHRONIC ARSENICAL POISONING

Symptoms—The gastro-intestinal symptoms—nausea, abdominal pain, vomiting and diarrhœa—are not prominent, and may even be absent. General malaise, anorexia and anaemia are usually present. If taken medicinally, or otherwise, over a long period, arsenic produces a finely mottled general brownish pigmentation of the skin—*raindrop pigmentation*. It affects principally the covered parts. The mucous membranes are not involved. Thickening of the epidermis of the soles and palms, and irregular thickening of the nails are present in long standing cases. Squamous carcinoma of the skin of the palms of the hands may follow. In some cases salivation is a marked feature, paroxysmal attacks of excessive secretion of saliva occurring. Erythema, herpes zoster, pigmentation of the skin or erythromelalgia, are commonly to be noted. Symptoms of multiple neuritis are likely to develop, and these affect both the upper and lower extremities.

Long continued poisoning causes anaemia, peripheral neuritis, progressive wasting and weakness, death resulting from exhaustion and cardiac failure, ascites and general

œdema occurring towards the end. Where the salts of arsenic settle in the skin of the workman in industry multiple neuritis does not occur. There is pharyngitis laryngitis with husky voice and conjunctivitis with redness and swelling of the eyelids. Hyperkeratosis with multiple papillomata and even multiple carcinomata of the skin may occur. Often there is perforation of the nasal septum which is symptomless unless carcinoma supervenes.

The urine, feces, the distal portions of the hair and the nails contain arsenic, its detection serving to confirm the diagnosis during life. The tests for arsenic will be found in works on toxicology. It must be remembered that in cases of suspected arsenical poisoning the diagnosis can always be made with certainty by an analysis of the urine, vomit and feces, and these should always be taken for examination, the tests being made by an expert toxicologist. It is important to remember that acute arsenical poisoning, where a large dose is taken, may (if the patient recovers from the acute attack) be followed by symptoms of chronic arsenical poisoning. Severe peripheral neuritis may follow acute poisoning from a single dose of arsenic.

Treatment—This consists in the prevention of the further absorption of arsenic. Dimercaprol (B.A.L.) injections usually have little effect. In the prevention of arsenical poisoning in industry dust must be suppressed. Workrooms should be well ventilated, and in all processes in which arsenical dust is likely to arise tables should be provided with downward exhaust ventilation. The wearing of respirators favours sweating and consequent ulceration of the skin. Instead the workmen must wear air-line helmets as well as gloves and washable suits. The floors of workrooms should be of impermeable material, and they should be frequently flushed with water. Neither food nor drink should be taken to the workroom and smoking should be prohibited.

3 ARSENIURETTED HYDROGEN POISONING

Ætiology—Arseniuretted hydrogen is a poisonous gas which is not manufactured in industry but is evolved as an accidental by-product in certain processes. The majority of cases have been due to the use of acids and metals contaminated with arsenic. The occupations concerned are the extraction of mineral ores, pickling and galvanising of metals, cleaning of acid tanks, the manufacture of hydrogen and its use in ballooning, and the making and charging of accumulators. Poisoning may arise from the action of water upon metallic arsenides. Cases have also occurred when ferrosilicon, a substance used for hardening steel, has come in contact with water, when a mixture of arseniuretted and phosphoretted hydrogen is evolved.

Pathology—The gas is inhaled and acts at once by hæmolyzing the red cells within the vessels. Hæmolytic jaundice and anæmia follow. Death may occur from anuria if the renal tubules become affected. Degenerative changes in the cells of the liver and kidneys, and numerous petechiæ on the mucous and serous membranes, are to be noted.

Symptoms—Malaise, headache, dizziness, shivering and hæmoglobinuria occur within a few hours. Within 24 hours there is nausea, vomiting and jaundice, and by the third day anæmia in which the red cell count may fall below 1,000,000 per c mm. Delirium, stupor and coma precede death.

Diagnosis—Mild cases are often mistaken for food poisoning. The sudden onset of hæmoglobinuria and jaundice at once suggests inquiry into a man's occupation.

Prognosis—Mild cases quickly recover. The mortality rate is 30 per cent.

Treatment—Workshops should be adequately ventilated and processes known to be risky should be forbidden in confined spaces. Sometimes a breathing apparatus suitable for use in irrespirable atmospheres must be employed. Such an apparatus consists of an oro nasal mask with tube connection to the outer atmosphere. The wearer draws fresh air through the tube by his inspiratory efforts and expels the expired air through a valve in the mask.

which is greatly increased in size. When death is delayed beyond 10 days the liver is small because of acute red and yellow necrosis, the so-called acute yellow atrophy.

Symptoms.—The clinical picture is divided into two periods with an interval of remission of symptoms. Usually 2 to 8 hours elapse between taking the poison and the onset of symptoms of the first stage. At the time the poison is taken a definite taste is noticed, with a sense of warmth in the mouth and throat. Then follow nausea, vomiting, burning abdominal pain, thirst, headache, subnormal temperature and a feeble pulse. Later there may be purging, but this is not constant. The abdomen becomes distended, and the patient is restless and exhausted. The vomit, which may contain blood, is sometimes luminous when examined in the dark. Rarely, delirium and convulsions occur followed by death. More often after 24 hours the condition improves. The period of remission may last as long as 6 days.

The symptoms of the second stage are jaundice, epigastric pain, vomiting and diarrhoea, sometimes with the passage of blood. There may be bleeding, especially epistaxis and menorrhagia, with hypoprothrombinæmia. On examination there may be purpura of the skin, the abdomen is distended and the liver enlarged and tender. Fever may be present at first but is variable. The pulse is normal and later becomes rapid, feeble and irregular. The urine is scanty and contains bile and often albumin and blood. The serum albumin falls and the globulin rises. The thymol turbidity and cephalin flocculation tests may be positive.

Prognosis.—Death takes place in 2 to 12 days, with an average of about 6 days. The liver is probably always enlarged at first, and should the patient die in a short time, this enlargement will be confirmed at necropsy. On the other hand, if the patient lives for a week to 10 days, the liver will be small and death will occur in hepatic coma.

Treatment.—If the patient is seen within the first 36 hours active measures should be taken to remove the poison from the stomach and intestines as rapidly as possible. Gastric lavage with large quantities of potassium permanganate solution, 1 in 500, should be performed and repeated a few hours later. Active purgation should be carried out, oily purgatives being avoided, and at the same time a high colon wash should be given. If the apparatus to perform gastric lavage is not to hand emetic doses of gr 10 to 15 of copper sulphate may be used. Should potassium permanganate be unobtainable other oxidising agents, such as solution of hydrogen peroxide (1 to 3 per cent), may be used. During the next few days oils and fats must be excluded from the diet. When jaundice has begun there is but little to be done, the treatment being symptomatic only.

2 CHRONIC PHOSPHORUS POISONING

Synonym—Phossy Jaw

Definition—A chronic disease characterised by necrosis of the mandible or superior maxilla with secondary osteomyelitis. Involvement of the long bones sometimes led to multiple spontaneous fractures.

Ætiology.—Although yellow phosphorus is no longer used in the manufacture of matches, it is made on a large scale for military purposes. Compounds of phosphorus are necessary in brewing, in food processing and for use as fertilisers. In paper-making, printing and the manufacture of baking powders, cellulose, dyes and soaps, phosphorus compounds are used in one form or another. The metaphosphates are of importance in water-softening, in the manufacture of detergents and in the processing of fibre. Organic phosphorus compounds are used as plasticisers and insecticides.

Matches made with yellow phosphorus were first manufactured in 1832 and within 15 years phosphorus necrosis of the jaw was identified in match factories in almost every civilised country. The poisoning was slow to occur, the average time of

onset after the man was first exposed being 5 years. Less than 5 per cent of those exposed acquired the disease. Some extremely susceptible patients were found who succumbed to the effects of the poison within a few months.

Symptoms—The first symptom was toothache usually in a carious tooth. A dull red spot on the buccal mucosa was the first sign of phosphorus necrosis of the jaw. At a later stage it was common to find a sinus, surrounded by dull red mucosa leading to a cavity beneath. Sequestra up to 1 cm in diameter were found. Later the pain increased in severity and swelling of the gum and jaw appeared. Suppuration occurred spontaneously or, more commonly, after dental extraction. If the worker returned to work too soon, and was again exposed to phosphorus, the inflammation spread rapidly. Chronic abscesses were then formed, and sequestra continued to separate over many years, sometimes involving the whole jaw. It was very painful and was accompanied by a fetid discharge which made its victims almost unendurable to others.

Prognosis—The disease was obstinate and chronic, the treatment was agonising and the final result was a distressing disfigurement. Sometimes extension of the suppuration to the orbit or meninges caused death, but more often this was brought about by septicaemia. The mortality rate was about 20 per cent.

Treatment—**PROPHYLACTIC**—Abolition came in 1906 when all the important countries of Europe agreed by the Berne Convention to forbid the manufacture and import of yellow phosphorus matches. Since 1855 the allotrope, red amorphous phosphorus has been used as the inflaming ingredient on the outside edges of boxes of safety matches. In the hundred years which have elapsed since that time red phosphorus has never produced phossy jaw or, indeed, any other harmful effect on the worker. Since 1900 in all countries the harmless phosphorus sesquisulphide has been used in the inflaming composition forming the heads of strike anywhere matches and no harm has ever come to the worker who handles it. Although the use of yellow phosphorus is prohibited in the manufacture of fireworks, it is still used in making smoke screens, incendiary bombs and hand grenades, as a constituent of rat poison and in the manufacture of phosphor bronze.

CURATIVE—Successful supervision of the worker handling yellow phosphorus demands examination of the teeth and jaws at regular intervals. A dental clinic with radiographic equipment and the services of dental surgeons is essential. Employees must be carefully selected. Not only must they have good general health, but also their teeth must be normal both clinically and radiologically. Radiographic examination of both jaws should be made before work begins and it must be repeated annually. The radiographs must be searched in detail for areas of decalcification indicating caries of bone. This is of special importance between the third to fifth years of employment. Records must be kept of all those exposed to the hazard, and it should be known which workers have been excluded permanently or temporarily from exposure.

When a sequestrum is found and removed, rapid and complete recovery follows. The dreadful sequelae of the neglected disease need never occur. Indeed, in Great Britain, during the War of 1939–1945, when the amount of yellow phosphorus manufactured for use in incendiary warfare exceeded all previous records, no case of phossy jaw developed.

3 POISONING BY TRI-ORTHO-CRESYL PHOSPHATE

Ætiology—Poisoning with tri-ortho-cresyl phosphate (TOCP) first occurred among patients with pulmonary tuberculosis who were treated with phospho creosote. The condition became well known because of an outbreak of polyneuritis, in 1930 in the United States of America among individuals who had partaken of a beverage known as *Jamaica ginger* or *jake*. Nobody knows why the drink was contaminated

by this chemical substance. In 1931 poisoning occurred in Holland in women who had taken apiol as an abortifacient. In many parts of the world people have been affected because they have eaten food accidentally contaminated. T.O.C.P. is manufactured for use as a plasticiser in the plastics industry. The first cases resulting from exposure in an industrial occupation occurred in 1944 and since then relatively few cases have been seen.

Pathology.—The poison inhibits the action of pseudo-cholinesterase—an enzyme present in the blood serum, the peripheral nerves and the white matter of the spinal cord, and distinct from the true cholinesterase which is present at the motor end-plates and in the red blood cells.

Symptoms.—The clinical picture develops by three stages. (1) In some cases there are transient gastro-intestinal symptoms, including nausea, vomiting, diarrhoea and abdominal pain. These often clear up, and a symptom-free interval follows, lasting from 5 to 21 days, the average being 10 days. (2) This interval is followed by soreness of the muscles below the knees and numbness of the toes and fingers, lasting for several days and followed by weakness of the toes and bilateral foot-drop. (3) After another interval of about 10 days, weakness of the fingers and wrist-drop follow. This paralysis is not usually so severe as that in the feet and legs. In the upper extremities paralysis does not extend above the elbows. The thigh muscles may be involved in advanced cases. Loss of sphincter control is unusual. In severely poisoned patients, in addition to the peripheral motor nerves, the anterior horn cells, the pyramidal tracts and the spino-cerebellar tracts may be involved. Extreme muscular wasting tends to dominate the clinical picture in the early stage. When muscular activity is partially restored, the spastic signs of the previously hidden upper-motor-neurone lesion become apparent. In such cases the end-result resembles amyotrophic lateral sclerosis.

Prognosis.—Improvement may be slow to the point of exasperation but it often exceeds expectations. Thus a patient paralysed in both lower limbs for 18 months was able at the end of that time to walk unaided.

Treatment.—**PROPHYLACTIC.**—To prevent absorption through the respiratory tract, all rooms where T.O.C.P. is handled should be provided with exhaust ventilation. Tanks should be enclosed and the vents fitted with ejectors, so that the vapours may be quickly transferred to the open air. Measures must be taken to prevent skin contact. Elbow-length gloves should be worn, and workers should change into special clothing during their working hours and take a bath at the end of the work period.

CURATIVE.—Splints may be needed to prevent overstretching of paralysed muscles. Massage, physiotherapy and appliances such as shoes with uplifting toe-springs may be necessary.

4. POISONING BY ORGANIC PHOSPHORUS INSECTICIDES

Ætiology.—Since 1946, organic compounds of phosphorus have been used as insecticides for the control of insect pests, such as aphids and red spider. Preparations in common use contain tetra-ethyl-pyrophosphate (T.E.P.P.), hexaethyltetraphosphate (H.E.T.P.), diethyl-*para*-nitrophenylthiophosphate (*Parathion*, E.605 f., D.P.T.F., or *Bladan*), octamethyl pyrophosphoramidate (*Schradan* or O.M.P.A.) and *bis*-mono-isopropyl aminofluorophosphine oxide (*Mipafax*). Preparations include liquid sprays, dusts and wettable powders which are diluted before being applied in greenhouses, orchards and fields.

Pathology.—Insecticides containing organic compounds of phosphorus are poisonous to man and animals. They are related in chemical structure and physiological action to di-isopropyl-fluorophosphonate (D.F.P.), which is a powerful cholinesterase inhibitor sometimes used in the treatment of myasthenia gravis, paralytic ileus and

glaucoma. The insecticidal properties of T.E.P.P., H.E.T.P. and Parathion are similar to those of nicotine. The effects of H.E.T.P. are almost certainly due to contamination of the manufactured product by T.E.P.P. Schrader and Mipafox are systemic insecticides, that is to say they have no direct insecticidal action nor do they inhibit cholinesterase *in vitro*. They are converted in the plant or animal tissues and are effective as insecticides only against pests which eat the plants. In a single dose they are less toxic than nicotine, but the effects of absorbing small amounts of these anti-cholinesterase substances are prolonged and result in increased susceptibility to absorption of further amounts of any cholinesterase inhibitor. All types of preparations penetrate rapidly through the skin, producing only slight irritation at the site of absorption. Exposure to as little as 0.3 g. daily has been estimated as dangerous to man. The lethal dose by mouth for man is approximately 100 mg. of T.E.P.P. or Parathion, and symptoms follow the administration of more than 10 mg. Absorption may also occur from inhalation and ingestion.

Symptoms.—The early symptoms of poisoning are mild and non-specific and may include headache, nausea, anorexia and unusual fatigue. These may be accompanied by pin-point constriction of the pupils. The symptoms are aggravated by smoking or taking food. From 2 to 8 hours later, nausea, abdominal cramps, vomiting, diarrhoea, muscular twitching, coma, convulsions and signs of pulmonary oedema may develop. Incontinence of urine and faeces is common. Death may result in as short a time as one hour after the onset of symptoms.

About 3 weeks after recovery from the acute phase of the illness, patients may develop paralysis of the limbs similar to that which follows poisoning by tri-ortho-cresyl phosphate. Therefore, all patients who have had acute poisoning by organic phosphorus compounds should be kept under close observation until the cholinesterase activity of the blood has returned to normal.

Treatment.—**PROPHYLACTIC.**—Strict precautions are necessary to protect workers engaged in handling these insecticides. Protection is more easily arranged and applied in factories than in field operations. In factories where an organic phosphorus insecticide is made, mixed with wetting agents, or incorporated in dusts or wettable powders, exhaust ventilation should secure that this substance is absent from the atmosphere. Protective clothing must include overalls, gloves, boots, cap and underwear, which are laundered each day and changed immediately if accidentally splashed. Ordinary clothing must be protected from possible contamination. Respirators should be available in factories for use in emergency; in field operations they must be worn during dusting operations and the diluting of wettable powders. It is necessary that the workers should wash thoroughly before eating or smoking, and a bath should be taken at the end of a day's work. These instructions, together with an account of the symptoms of poisoning, must appear on the labels of containers of organic phosphorus compounds. The attention of all workers exposed to risk should be directed repeatedly to the toxic properties of these compounds.

Regulations under the Agriculture (Poisonous Substances) Act, 1952, prohibit the use of organic phosphorus compounds unless the men working with them are wearing protective clothing. The number of hours during which workers can be employed are restricted to 10 hours in any one day and 60 hours during seven days. The employment of any worker under the age of 18 is prohibited. The regulations also contain requirements about the provision and maintenance of protective clothing, the provision of washing facilities for workers, the notification of sickness and absence, the training and supervision of workers, and the keeping of registers. Unhappily, no provision is made for the estimation of the blood-cholinesterase activity at frequent intervals of people at risk.

CURATIVE.—Atropine is an antidote to the muscarinic and central-nervous-system effects of this form of poisoning. It should be given in doses of 1 to 2 mg. ($\frac{1}{16}$ to $\frac{1}{8}$ gr.) at hourly intervals until the pupils are dilated. Oxygen, under slight pressure

to overcome bronchial spasm, should be administered at the first sign of pulmonary œdema. The fibrillary twitching of rouscles appears to affect particularly the diaphragm, and artificial respiration may be necessary. Involvement of striated muscle is the result of the nicotine like action of these compounds. No antidote to this effect is known and death may occur from neuromuscular paralysis, even though the muscarine like effects and the signs of involvement of the central nervous system have been controlled by atropine.

MERCURIAL POISONING

1 ACUTE MERCURIAL POISONING

This usually arises from the absorption of mercuric chloride, also known as corrosive sublimate (HgCl_2), which is largely used in medicine as a disinfectant or antiseptic. Bimodide of mercury has similar uses. Both are usually purchased in the form of tablets ready for solution in a required amount of water. Acute poisoning generally occurs from the taking of the poison by the mouth, but it may also arise from the use of mercuric compounds in solution as uterine or vaginal douches. Grains 5 of mercuric chloride is a fatal dose for an adult, unless the poison is removed by gastric lavage within an hour or two. Calomel (mercurous chloride), even if taken in large doses, does not give rise to the same degree of acute poisoning, owing to its insolubility. Cases are known in which over gr 100 of calomel were taken with suicidal intent, and beyond some vomiting and diarrhœa, little harm resulted.

Symptoms—If mercuric chloride is swallowed in tablet form there is risk of local corrosion and perforation of the stomach, with rapidly fatal result. When taken in solution, or in tablet form with water, or on a full stomach, an acid metallic taste is experienced, followed by a sense of constriction in the throat. A hot burning sensation occurs in the mouth and œsophagus. Acute abdominal pain and vomiting take place. The vomit contains mucus and often blood. Diarrhœa and tenesmus occur. Collapse is associated with these early symptoms. The mouth and pharynx may show white swollen patches, which may be followed by sloughing. Unless the poison is quickly removed by gastric lavage dangerous sequelæ rapidly follow. The condition is always accompanied by a very severe stomatitis, which begins within a few hours. The breath is foul, the mucous membrane becomes ulcerated, the teeth may become loose and necrosis of portions of the jaw occurs.

Later effects of acute mercurial poisoning are (1) suppression of urine due to the action of mercury on the renal epithelium causing cloudy swelling and even necrosis, and (2) ulcerative colitis, the result of extensive necrosis and sloughing of the mucosa of the colon. Suppression of urine is followed by a rapid rise in the blood urea, and after 4 or 5 days symptoms of uræmia such as vomiting, stupor, delirium, coma and convulsions appear. The ulcerative colitis begins about 24 hours after the intake of the poison, and is associated with profuse diarrhœa, and the passage of sloughs and shreds of necrotic mucous membrane and blood. The colitis may be caused by the absorption of mercury into the blood stream apart from its direct local action on the colon. Death may occur from dehydration and exhaustion.

Treatment—Immediately the patient is seen the stomach must be washed out with 4000 ml of 5 per cent sodium formaldehyde sulphonylate. Without delay 300 mg of a 10 per cent solution of dimercaprol (BAL) in benzyl benzoate and arachis oil must be injected intramuscularly. This treatment is followed within the first 12 hours by two or even three further injections each of 150 mg of dimercaprol. Subsequently a daily injection of 150 mg of dimercaprol is given for 2 or 3 days according to the general condition of the patient. Where there is shock with hæmo-

concentration it is necessary to use intravenous infusions of physiological salt solution with 5 per cent glucose. Blood transfusion may sometimes be required.

Prognosis.—Where treatment has been carried out within 3 hours of swallowing the poison, the patient will be free from symptoms in 48 hours, and will have recovered entirely within 3 to 7 days. Treatment with dimercaprol has reduced the mortality rate of acute mercurial poisoning from 32 per cent to 4 per cent.

2 CHRONIC MERCURIAL POISONING

Ætiology.—This condition occurs chiefly amongst workers in the metal, or amongst those who are constantly brought into contact with compounds of mercury, for example, those engaged in mining and separation of the metal, *e.g.* at Almaden in Spain, at Idria in Yugoslavia, and at mines in Italy, California, Mexico, China and Russia. Mirror makers, thermometer and barometer makers, and those engaged in the manufacture of chemical and electrical apparatus in which metallic mercury is used, are exposed to risk. Those engaged in the frequent handling or grinding of mercury compounds are sometimes attacked. It must be remembered that mercury is volatile at ordinary temperatures, and those working in ill-ventilated rooms where mercury is exposed are liable to attack. Cases have been recorded of chronic mercurial poisoning from the amalgam in tooth stoppings, and from sojourn in a respiration apparatus fitted with mercury air-valves. The nitrate of mercury is used in the felting of fur, and hatters' furriers are liable to chronic poisoning unless they are properly protected. The condition may result from the continued administration of calomel or blue pill, from theunction of mercury ointment, or from the prolonged use of mercurial vaginal douches. The effects of overdosage by preparations of mercury used in the treatment of syphilis are described on p. 233.

Symptoms.—Dyspepsia, anæmia, general cachexia, with loss of weight and strength occur. Sometimes a blue line is seen on the gums if the teeth are neglected. Stomatitis is one of the most constant symptoms, increased salivation and marked fetor of the breath occur, and are associated with tenderness of the gums and looseness of the teeth. Colitis, often of an ulcerative type, may result from the continued

filled without suitable exhaust-ventilation for the removal of mercury vapour. Overalls, mess-rooms and washing facilities are provided. The mouth and pharynx are frequently rinsed with a mouth-wash, and the teeth cleaned with a soft toothbrush and a dentifrice. Periodical medical and dental examination can achieve a great deal, especially by emphasis on the proper hygiene of the mouth. Cavities in carious teeth are filled, sharp angles smoothed, and stumps and teeth irretrievably decayed extracted. In the felt-hat trade the workshops must be well managed and spotlessly clean. Efficient exhaust-ventilation must be applied to remove the particles of fur and all vapours of mercury compounds at the source of origin. A workman affected by mercurial tremor must give up his work, and abstain from alcohol. Stomatitis should be treated by the use of the toothbrush, mouth washes and dental extractions when necessary. In cases of medicinal poisoning saline aperients should be given daily to promote the free elimination of mercury by the colon.

3. POISONING BY MERCURY FULMINATE

Mercury fulminate is handled in explosives factories where detonators and percussion caps are made. In those processes where the fine dust of this substance falls upon the skin, dermatitis follows. The susceptibility of some individuals is such that they cannot stand the dust for a day, whereas others only suffer in warm weather. As a rule, the cases of "fulminate itch", as they are called in the trade, are slight. The face, eyelids, neck and forearms are attacked by erythema, accompanied by itching, swelling and œdema. Papules break out on the inflamed areas, and may become vesicles, bullæ and pustules. A pustular folliculitis commonly develops on the hairy parts of the skin. If the fulminate lodges in a crack or abrasion of the skin it may act as a corrosive, causing small painful necrotic lesions on the hands which last about a fortnight. The operatives call them "powder holes". Recovery takes place in from 1 to 2 weeks and is accompanied by desquamation. Inflammation of the conjunctivæ and mucous membranes of the nose and larynx may occur.

In the manufacture of mercury fulminate meticulous attention should be paid to detail in all matters of cleanliness in the entire plant. Where fumes are given off as the result of small explosions they must be removed by means of mechanical ventilation. All persons employed should be provided with well-fitting overalls, caps, india-rubber gloves and, if necessary, respirators. Washing accommodation must be available close to the workroom, and a separate towel provided for each worker. The hands and arms are washed before meals and before leaving work in a 10 per cent. aqueous solution of sodium thiosulphate. A lanolin ointment is rubbed into the skin after washing. For the conjunctivitis a 2 per cent. solution of sodium thiosulphate as an eyewash has been beneficial.

4. POISONING BY ORGANIC MERCURY COMPOUNDS

Fungicidal dusts containing organic mercury compounds are used extensively in agriculture to prevent certain smut diseases of cereals. For some years mercurial derivatives of the phenyl and tolyl series have been manufactured without any mishap worse than an occasional burn on the skin. Poisoning by inhalation of methyl mercury compounds leads to involvement of the nervous system in a unique way, salivation, stomatitis and crethism being absent. There is severe generalised ataxia, dysarthria and a gross constriction of the fields of vision, memory and intelligence being unaffected. In severe cases the patient remains crippled, and unable to stand or to speak intelligibly. The condition has been reproduced experimentally in the rat and the monkey; here degenerative changes involved the spinal cord and peripheral nerves. In a patient who died 15 years after exposure had ceased necropsy showed

atrophy sharply localised to particular areas of the cerebellum and the occipital cortex. The spinal cord and peripheral nerves were unaffected.

In the manufacture of organic mercury compounds elaborate precautions must be taken to prevent contact with the skin or inhalation. The use of gloves and respirators is not enough. The whole process of manufacture, including the final packing of the dusts, must be carried out mechanically in closed apparatus. The farmer should be protected both by warnings that mercurial dressings are poisonous and by schemes whereby he can obtain from the merchant seed already dressed. The seed merchant must dress the seed in a completely closed apparatus. The ataxia and dysarthria of methyl mercury poisoning must be treated by re-educative movements, persuading the patient to walk on chalked lines. An expert in charge of a speech clinic with great patience and the use of a mirror should teach the workman to speak. With great perseverance in some cases he may be taught to use knife and fork, a pencil and even a typewriter.

CHROMIUM POISONING

Chromium is a silver-white, hard, brittle metal. It is an essential component of the alloys known as stainless and rustless steels. The only commercial use of pure chromium metal is in the form of electroplate.

Ætiology and Pathology.—Both in the chromium plating of metals and in the anodising of aluminium, the solution used contains chromic acid. During electrolysis the evolution of hydrogen at the cathode forces into the atmosphere a reddish-brown mist which contains 60 per cent. of chromic acid. Together with dust from chromates or bichromates this mist is the principal source of exposure in industry.

Symptoms.—*Acute poisoning* is confined to an occasional case of chemical pneumonitis.

Chronic poisoning is common and affects the skin. Exposure may cause either diffuse dermatitis or localised ulceration, according to whether trauma is present or not. The dermatitis appears on the hands, face, arms and chest.

Chrome ulcers begin in abrasions of the skin, and are most commonly found at the root of the finger-nail, the knuckle of the hand or the dorsum of the foot. They are circular in shape, clear-cut, usually 1 cm. or less in diameter and look as if punched out, hence the name *chrome hole*. These ulcers have a strong tendency to heal but may penetrate even as deep as bone. Although painless, they itch intolerably at night. If neglected, an ulcer may lead to infection of the adjacent joint, causing loss of the finger. Malignant change does not occur. Ulcers on the eyelids or the edge of the nostrils may occur. Irritation of the conjunctiva may be severe. The mucosa of the nose is commonly affected with perforation of the nasal septum. The process begins with sneezing, rhinorrhœa and slight pain. Once the perforation is established, the only inconvenience is the formation of plugs of mucus in the nasal passages. At this site, again, malignant changes do not occur.

The statistical study of mortality data and hospital records suggests that the incidence of carcinoma of the lung is unusually high in men employed in the chromate-

peculiar care Weekly inspection of the nasal passages should be carried out by the factory nurse for all workers

CURATIVE—The exposed skin should be washed and carefully dried Application of an ointment made up of equal parts of lanolin and soft paraffin is useful Soft paraffin should be freely applied through the anterior nares to the nasal septum

MANGANESE POISONING

Ætiology—Manganese is used in the manufacture of dry batteries and in the pottery, soap and colour industries Cases of poisoning have followed upon the inhalation of excessive amounts of dust in the grinding, sieving and packing of manganese ores, and in the manufacture of manganese steel in which the metal is first fused in the electric furnace

Pathology—Susceptible individuals are few There is a similarity between this form of poisoning and progressive lenticular degeneration, except that in manganese poisoning the condition remains stationary or improves when exposure to manganese dust ceases Histological studies on necropsy material have shown degenerative lesions of the nerve cells particularly in the globus pallidus the lenticular nucleus and the caudate nucleus The fact that histological lesions have been found in the liver makes still closer the connection between poisoning by manganese and progressive lenticular degeneration The condition has been reproduced experimentally in monkeys by administering manganese chloride by intraperitoneal injection The animals developed choreic movements, passed into a state of rigidity and finally developed tremor resembling paralysis agitans Gross morbid changes were found in the lenticular nucleus and liver The experiments afford an explanation of the symptoms in most of the cases described The extrapyramidal motor system is clearly picked out by the poison, hence the rigidity, difficult gait, retropulsion, propulsion, mask like facies, sleepiness, tremor and uncontrollable laughter

Symptoms—The symptoms include languor and sleepiness, low monotonous voice, mask like facies involuntary movements varying in degree from a fine tremor of the hands to gross rhythmical movements of the arms legs trunk and head, cramps in the calves, retropulsion and propulsion unsteady gait and occasionally uncontrollable laughter or crying There is no disability except in the nervous system

Prognosis—Although men seriously poisoned are life long cripples, the condition is not lethal

Treatment—Manganese poisoning can be prevented by wearing respirators wherever dusts or vapours are encountered Personal hygiene is important and the worker must wear protective clothing and gloves, since the occurrence of skin absorption is established Local exhaust ventilation should be applied, both at the furnaces to remove fumes and at the packing and sieving apparatus to remove dust These measures are attended with good results for it has been found that when they were applied in one particular factory they removed all risk of poisoning encountered by the workers over a period of 6 years

BERYLLIUM POISONING

Beryllium is a very light, hard, shiny metal which forms important alloys Beryllium copper is hard resistant to corrosion non rusting non sparking non magnetic and it has great tensile strength Metallic beryllium is employed in steel making and in the construction of atomic piles

Ætiology—Occupations involving exposure to beryllium compounds include the extraction of the metal from the ore, the preparation of beryllium steel and the manufacture and cutting of beryllium copper alloys A hazard exists in preparing the

complex beryllium salts used as phosphors for coating the tubes of fluorescent strip lamps

Symptoms—Symptoms attributable to exposure to beryllium compounds can be divided into six groups, of which the first five constitute acute berylliosis and the sixth chronic berylliosis

(i) *Conjunctivitis* is frequently associated with dermatitis of the face. On removal from contact the lesions readily heal

(ii) *Tracheitis and bronchitis*—Anorexia may be followed by tracheitis and bronchitis and there may be loss of weight

(iii) *Dermatitis*—A severe oedematous papulo-vesicular eruption may appear mainly on the exposed surfaces

(iv) *Subcutaneous granulomata* occur when beryllium compounds are introduced beneath the skin. Such lesions may occur in persons who have cut themselves on broken fluorescent lamps. The granuloma may measure as much as 2.5 cm in diameter

(v) *Acute pulmonary disease*—Cough with bloodstained sputum is accompanied by retrosternal pain, dyspnoea, cyanosis and loss of weight. Rapid respiration, anorexia and marked prostration follow. Usually there is no fever, but cyanosis and tachycardia are present, and râles are heard over both lungs. Resolution begins in the third week of the illness and is complete in from 5 weeks to 5 months. In severe cases death occurs within 2 weeks. At necropsy the lungs show alveoli filled with exudate composed of oedematous fluid and fibrin. In cases in which death has occurred after several weeks there are areas of organising pneumonia. Sometimes an attack of the acute illness is followed by the onset of chronic lung disease after 2 years

(vi) *Chronic pulmonary disease*—The first symptoms of chronic berylliosis may not appear for as long as 6 years after cessation of exposure. Less than 5 per cent of all persons exposed to dusts of beryllium compounds have developed this disease. The onset is with vague ill-health followed by weakness, anorexia, cough, extreme dyspnoea and progressive loss of weight, which may be as much as 20 to 30 pounds in a month. Clubbing of the fingers develops in the later stages. Persistent tachycardia may be followed by congestive heart failure

The earliest change in the radiograph is a diffuse finely granular appearance, homogeneously distributed throughout both lungs. Later a fine nodulation appears on a granular background and there is lobular emphysema, particularly at the apices and bases. At necropsy the lungs are emphysematous with scattered fine nodules and diffuse interstitial fibrosis. Granulomata are formed within the alveolar spaces, in the skin and subcutaneous tissues and sometimes in the hilar and axillary glands and in the liver

Prognosis.—In chronic berylliosis approximately 33 per cent of the patients die, and 33 per cent are permanently disabled and remain in great pulmonary distress. The rest lose their symptoms, the lung changes resolving to some extent

Treatment—**PROPHYLACTIC**—In the manufacture of fluorescent lamps, halo phosphates, which contain no beryllium, must be used in place of the poisonous phosphors formerly used. Where beryllium and its compounds are handled every effort must be made by engineering methods to keep the atmosphere concentration at the lowest possible level. Protective clothing and adequate laundry services should be provided. Since subcutaneous granulomata have developed in persons who have cut themselves on broken lamps, caution must be exercised in the disposal and salvage of burnt-out fluorescent lamp tubes. Workers at risk should be seen at regular intervals by a doctor and questioned about suggestive symptoms. They should be weighed at monthly intervals, and have their chests radiographed at least once a year

SYMPTOMATIC—In severe cases oxygen should be used for the relief of dyspnoea

SURGICAL—Any granulomatous mass in the skin must be completely excised, otherwise healing may be long delayed

CADMIUM POISONING

Cadmium is resistant to corrosion and withstands wear. The metal and its alloys are therefore used in many manufacturing processes. The principal industrial hazards arise in the smelting of ores, the manufacture of alloys, the welding of cadmium-plated metal and the manufacture of alkaline accumulators.

Cadmium poisoning occurs from domestic causes—by ingestion—or from exposure in industry—by inhalation.

1 BY INGESTION

Ætiology and Pathology.—The careless use of cadmium coated vessels as containers for food and drink may lead to acute poisoning.

Symptoms.—The symptoms appear suddenly within 15 minutes to 2 hours after ingestion, and everybody who has eaten the contaminated food is affected. Increased salivation, severe nausea and vomiting are the first symptoms. In severe cases there is collapse with signs of shock, and sometimes hæmatemesis. Later diarrhœa occurs, sometimes with tenesmus. Recovery usually takes place within 7 hours and is invariably complete within 24 hours.

Treatment.—**PROPHYLACTIC.**—Anti rust treatment by cadmium plating of the trays of domestic refrigerators should be abandoned.

SYMPTOMATIC.—Beyond fluid replacement no treatment is required.

2 BY INHALATION

Ætiology and Pathology.—When cadmium is heated, copious brown fume of the oxide is evolved. This attacks the structures of the respiratory tract. In acute cadmium poisoning, necropsy shows hyperæmia of the bronchi, gastro intestinal tract and kidneys, and in severe cases confluent broncho pneumonia. Necropsy in cases of chronic cadmium poisoning shows chronic vesicular emphysema, toxic nephrosis and fatty degeneration of the liver.

Symptoms.—In *acute poisoning*, the symptoms include irritation of the eyes, headache, vertigo, nausea, dryness of the throat and cough with pain in the chest. Delayed effects may follow after an interval of a few hours, and these include shivering, sweating, nausea, epigastric pain and severe dyspnœa, which may be aggravated by the development of broncho pneumonia. Chronic rhinitis with complete anosmia is frequently found. A *chronic disease* may occur in men exposed to small quantities of cadmium in the working atmosphere for long periods. The striking feature of this disease is severe pulmonary emphysema, giving rise to dyspnœa on exertion. Proteinuria, detected by testing the urine with 25 per cent nitric or trichloroacetic acid occurs in a large proportion of cases. This protein is distinct from both albumin and Bence Jones protein and has a very low molecular weight. A golden yellow ring develops on the teeth of workers after 2 or more years' exposure, and is an index of absorption of, but not of poisoning by cadmium.

Treatment.—**PROPHYLACTIC.**—In the smelting of cadmium ores, the welding of alloys and the firing of cadmium plated metal, precautions should be taken to remove all fume by means of adequate exhaust ventilation. It has been suggested that all cadmium coated metal should bear a warning label. While this measure is effective for large pieces, it is somewhat difficult to ensure that small objects so coated are labelled.

SYMPTOMATIC.—Symptomatic treatment is directed specifically against pneumonia when it occurs.

POISONING BY COAL-TAR DERIVATIVES

The coal-tar derivatives are so numerous and complex that it is difficult for the toxicologist to keep pace with the chemists who produce them. The following compounds will be discussed; benzene, nitrobenzene, dinitrobenzene, trinitrotoluene, dinitrophenol, dinitro-*ortho*-cresol, aniline and phenylenediamine. It is sometimes possible to predict from the chemical composition of the simpler members of the group what their physiological action is likely to be. Addition of a nitro- or nitroso-group usually produces a more toxic compound, but it does not follow that toxicity will continue to increase as more nitro-groups are added. Thus, 1-2-4 dinitrophenol is toxic, whereas trinitrophenol is practically harmless. The position of the substituent groups in the benzene ring has a great effect on the toxic action. Thus, the toxic properties of 1-2-4 dinitrophenol are not shared by any of the other isomers. When a nitro-compound is reduced to an amine, as when nitrobenzene is reduced to aniline or nitrotoluene to a toluidine, the toxic characteristics remain much the same, but the intensity of the action is lessened. Sulphonation renders a compound non-toxic; as soon as aniline is sulphonated it ceases to give trouble. The entrance of chlorine into an aromatic compound does not usually increase the toxicity, as it does in the case of an aliphatic compound. In fact, chlorobenzene is less toxic than benzene.

1. BENZENE

Coal-tar benzene or benzole is obtained as a by-product from the distillation of tar in the manufacture of coal gas. It is the most interesting of the industrial solvents, and with the exception of tetrachlorethane the most dangerous. It must not be confused with benzine, which is unfortunately pronounced in the same way. Benzine is derived from the distillation of petroleum and is non-toxic. Coal-tar benzene has two fields of application in industry: (1) where it is handled in large quantities in closed mechanical systems, as in the distillation of coal-tar, the blending of motor fuel and in chemical industry; and (2) where it is used as a solvent, as in the rubber industry, artificial leather manufacture, the dyeing and cleaning industry, the manufacture of paints, varnishes, celluloid, artificial manure and glue.

Acute benzene poisoning usually occurs as the result of the breaking of distilling apparatus, or in the cleaning of tanks. In slight cases there is giddiness, and a stage of excitement; in severe cases these symptoms may be followed by convulsions, coma and death. Benzene sinks into the metal of tanks. It is therefore necessary to forbid men to enter such tanks until they have been washed clean and exposed to the open air for many days. Even then a workman lowered into such a tank must be equipped with body belt, life-line and breathing apparatus communicating with a hose to the exterior. In the stage of excitement the victim may shriek, sing madly and fight with the rescuer, who, on account of his greater exertions, runs more risk than the rescued.

Chronic benzene poisoning has always been very rare in Great Britain. Speaking for the whole world, however, it was at one time the most important industrial poison after lead. Benzene poisoning may begin with giddiness, nausea, anorexia, weakness and nervousness. These symptoms are followed by progressive anaemia, with hæmorrhagic manifestations, such as bleeding gums, epistaxis, menorrhagia, purpura and visceral and retinal hæmorrhages. Ulcers or gangrenous patches on the lips, fauces and pharynx are common. Although poisoning may occur only after many years' exposure there have been fatalities after a few weeks' exposure. The victims of industrial poisoning often constitute a small minority of the workers; a single susceptible individual may contract fatal poisoning in an environment which does not give rise to even mild poisoning in others. The factors responsible for the great

variations in susceptibility are largely unknown, but in general, women, especially young women, are more susceptible than men. Changes in the blood may begin from 2 days to 1 month after the first exposure, according to the amount absorbed, and they may progress, or even develop, after exposure has ceased. Acclimatisation to the vapour of benzene does not seem to occur, and it is doubtful whether any concentration greater than zero is safe over a long period of time.

The bone marrow is attacked, and it may be aplastic, normal, hyperplastic or leukaemic, the corresponding changes being reflected in the peripheral blood. In the early stages of poisoning there may be little or no evidence of damage to the red cells but only purpura with leucopenia and granulopenia. The total leucocyte count may fall to a very low level, in fact, the white cells may almost disappear. A count of 1000 per c mm is common. In some cases the granular leucocytes fall as low as 10 per cent. The bleeding time may be increased to half an hour, with a corresponding drop in the platelets. The red cell count may fall as low as three quarters of a million per c mm. Splenomegaly may appear in protracted cases of poisoning. Myeloid leukaemia, confirmed by post-mortem examination, has been found in several cases. Necropsy usually shows aplasia of the bone marrow. Haemorrhages may be found in the skin, pericardium, pleura, alimentary tract, meninges, bladder and uterus. Gangrenous stomatitis and even necrosis of the gastric mucosa have been recorded. Benzene cannot be discovered in the body after death.

Benzene is so toxic that its substitution wherever possible by other solvents which are harmless is, in preventive treatment, the method of first choice. In all processes involving the presence of benzene the value of frequent periodical medical examination, including examination of the blood, has been proved by experience. The more complete and effective the prevention of the escape of vapour into the workrooms, and the more efficient the daily supervision of the ventilating apparatus, the less is the necessity for periodical medical examination.

In acute benzene poisoning the usual methods of resuscitation are used—rest, warmth, artificial respiration, administration of oxygen and injection of nikethamide as a respiratory stimulant. The patient should be prevented from returning to work too early.

Cases of chronic benzene poisoning must be treated by repeated blood transfusions, and it must be remembered that the toxic influence may persist even after removal from exposure. The results of treatment are so poor as to convince all who have studied the subject that the use of benzene in industry must be ruthlessly suppressed, except where the process used is entirely enclosed. Fortunately in Great Britain it has been possible to do this.

2 NITROBENZENE

Nitrobenzene (mono nitrobenzene, oil of mirbane, artificial oil of bitter almonds) is used in the manufacture of aniline, in perfumery and as a flavouring agent, being the chief substitute for oil of bitter almonds. It is sometimes taken as an abortifacient, and on several occasions 15 to 25 drops have proved fatal, especially if the poison is taken with alcohol. The stomach should be washed out repeatedly with water until the returned fluid no longer smells of nitrobenzene. Purgatives should be given. In factories death has taken place from absorption through the skin, where the oil has been spilled on the clothing. The victim of such an accident should be stripped promptly of his clothes, sponged with weak acetic acid or vinegar and provided with a shower bath and clean clothes. The symptoms vary according to the acuteness of the poisoning. Pallor appears, quickly followed by lividity. Unconsciousness occurs with great rapidity, perhaps in 20 minutes. The patient is generally deeply cyanosed, and the blood is dark and viscid, and will sooner or later show the spectrum of methaemoglobin. Death occurs in coma, or recovery takes place after a variable period of unconsciousness. However, nausea and vomiting may begin again after a few days,

and toxic jaundice appear. The blood picture is that of anæmia with granular degeneration of the red cells (stippling), and sometimes the presence of nucleated red cells. In severe anæmia a blood transfusion may be considered.

3 DINITROBENZENE

Dinitrobenzene is used in the manufacture of dyes, and is itself an important explosive. It is a solid, and in consequence poisoning develops less rapidly and is less severe than in the case of mono nitrobenzene. Poisoning occurs amongst men who either shovel or melt dinitrobenzene. In a mild case there is a sense of pressure in the head, which increases to a violent throbbing headache, giddiness and dyspnoea. In severe cases the face is deeply cyanosed, the lips, tongue and ears are deeply purple, and there are nausea, sometimes vomiting, abdominal pain, a staggering gait and extreme weakness. An attack rarely occurs during work, the man is usually overcome some hours after he has left the plant. Cyanosis occurs, and is accompanied by anæmia with marked stippling of the red cells. Methæmoglobin, porphyrins, hæmoglobin and even albumin have been found in the urine. The smoky colour of the urine may be noticed by the men themselves soon after their first contact with nitrobenzene or aniline. Only very rarely does toxic jaundice occur. It is well known in industry that cases of poisoning are more frequent in hot weather than during the colder seasons of the year. Lack of care and unclean habits are predisposing causes. Those who do not change their working clothes on returning home may sit before the fire and absorb the poison from the evaporation of crystals or from the material in solution on their clothing. Absorption from the alimentary canal is more rapid if the stomach is empty, and it is therefore desirable that men should take a meal before they work. Alcohol undoubtedly favours absorption, and several instances are on record in which poisoning has supervened after indulgence in ordinary amounts.

4 TRINITROTOLUENE

Trinitrotoluene is handled mainly in the filling of shells. The first symptoms of poisoning are drowsiness, headache, nausea, loss of appetite, epigastric pain, vomiting and giddiness. There is some cyanosis of the lips, followed by dyspnoea with marked drowsiness and staggering gait. Dermatitis in the form of a diffuse erythema sometimes occurs on the dorsal surfaces of the wrists, and on the face and neck. The symptoms come on gradually after several days' or weeks' work, or they appear on a hot day after a few hours' work and cause collapse. If cyanosis occurs in 1 in 10 of the workers, toxic jaundice probably affects 1 in 500. The greatest incidence of jaundice is in the third month of employment. Premonitory symptoms, such as drowsiness, giddiness, depression and dark urine are sometimes present, but the onset is often quite sudden. Sometimes a latent interval occurs between removal from exposure and the onset of jaundice. The prognosis is always uncertain, but grave symptoms of hepatic insufficiency sometimes appear rapidly. The mortality is 25 per cent. The morbid appearances are those of yellow and red necrosis of the liver, with great reduction in its size and weight. The necrosis of the liver cells is associated with infiltration and subsequent fibrosis resembling ordinary portal cirrhosis. Aplastic anæmia sometimes occurs among trinitrotoluene workers, but its incidence is very small. The latency of the blood changes is even longer than the latency of the jaundice for it is found that anæmia can develop as long as 9 months after exposure to trinitrotoluene has ceased. The anæmia is usually, if not always, fatal. At necropsy fatty marrow is found throughout all bones. There is an excess of iron pigment in the liver, and multiple hæmorrhages are found in the tissues. The skin is the main channel of absorption. Experience in industry goes to show that when a poison is absorbed by this route the application of preventive measures is most difficult. The

principles involved are cleanliness of the air breathed, secured by effective ventilation or filtration through an effective respirator, cleanliness of the implements used and cleanliness of the person secured by protective clothing and by personal attention to the skin. Filling factories must have their own laundries and each worker must have two lockers, one for his own clothing and the other for his protective clothing. Workers and supervisors must be specially trained for the job. Periodical medical examination is essential.

5 DINITROPHENOL

Of all the dinitrophenols it is only the 2-4 or *alpha* isomer which has toxic properties. It is a pale-yellow crystalline powder, which is used as an explosive, in the dye industry, and for the preservation of timber. Absorption takes place through the respiratory tract, the alimentary canal and the skin. Heat aids absorption and alcohol increases the incidence of toxic manifestations. DNP acts by stimulating the general metabolism. Workers show yellow staining of the face, legs and forearms, and especially of the palms and soles. Staining of those parts of the body which have not been in direct contact with the powder indicates a dangerous accumulation of the compound in the body. In a small proportion of workers a pink maculo-papular eruption appears on the exposed skin. Mild poisoning is characterised by lassitude, slight headache, night sweats and fatigue on the slightest exertion. Workmen may lose weight from the time that they first take up the work. Acute intoxication comes on suddenly, with a sensation of extreme weakness in the limbs and painful constriction in the chest, a burning thirst, abundant sweats, and an agitation and anxiety which are characteristic. Other signs are pallor, dyspnoea and scanty urine, which may be a deep orange colour owing to the presence of 2-amino-4-nitrophenol. In more severe cases death may take place within a few hours after a rise of temperature to 104° F or over. The victim has severe sweating, intense thirst and sometimes colic and diarrhoea. The basal rate of metabolism is increased to 200 per cent or more. The state of anxious terror and restlessness is followed by hyperpnoea, coma, convulsions and death. Necropsy reveals no characteristic lesion. When the dose is not fatal the symptoms rapidly decrease and many workers develop a tolerance to the poison. The workmen must be provided with a complete set of underclothing and overalls into which they change from their working clothes, a separate cubicle being provided for each man. Well-designed exhaust ventilation must be applied locally to take away the fumes in the melting of the compound and also in the filling of shells. Any dust that collects around the margin of the shell must be removed by a vacuum cleaner.

In 1933 dinitrophenol became widely used in the treatment of obesity, especially in the U.S.A. A dose of 3 mg per kg of body-weight will cause a rise in basal metabolic rate and loss of weight, unattended by tachycardia. Toxic symptoms were soon reported, including urticaria, exfoliative dermatitis, jaundice, peripheral neuritis, loss of power to discriminate between sweet and salt tastes, fullness in the ears, deafness, fall in blood pressure, albuminuria, neutropenia and fatal agranulocytosis. After dinitrophenol had been employed for 4 years, cataract was found to be a late complication of the use of the drug. It appears from 3 months to 18 months after the first dose is taken, the change is bilateral and the lens fibres alter so quickly that the cataract swiftly progresses to total blindness. This final disastrous effect of dinitrophenol brought to a close the unfortunate popularity of this drug.

6 DINITRO-ORTHO-CRESOL

The compound 4,6-dinitro *ortho*-cresol is a yellow solid, manufactured on a large scale as a weed killer, insecticide, ovicide and fungicide. It is applied in agriculture as an aqueous solution of the sodium salt, while for locust control it is used

as a dust or solution in oil. Its use in the treatment of obesity, although effective, has been given up because it is too dangerous.

D.N.O.C. may be considered to be about twice as toxic as dinitrophenol (D.N.P.). It is a cumulative poison in man and is eliminated slowly. Like D.N.P., its lethal effect is due to excessive stimulation of the general metabolism. At necropsy the changes noted are yellow pigmentation of all the tissues, dehydration, petechial hæmorrhages of the brain and lungs, and parenchymatous degeneration of liver and kidneys. A papular dermatitis is common in workers handling D.N.O.C., and nasal irritation and burns of the skin of the hands have been reported. The earliest symptom of poisoning is an exaggerated feeling of well-being, but this is difficult to assess. It is likely to be present when the concentration of D.N.O.C. in the blood is of the order of 20 micrograms per gram of blood. In severe cases unusual thirst, excessive sweating and fatigue are followed by weakness, high fever, tachycardia, anxiety and great hyperpnoea. The basal rate of metabolism may rise even as high as 400 per cent. There is loss of weight, perhaps 20 lb. in a few weeks. Severe liver damage has sometimes occurred but cataract has been recorded once only.

Measures adopted to reduce the incidence of D.N.O.C. poisoning include (1) periodical medical examination of the workers, (2) the introduction of locally applied exhaust ventilation in factories, (3) the use of masks, protective clothing and enclosed tractor-cabins by spray operators, and (4) the exclusion from further contact, for at least 6 weeks, of workers in whom the concentration of D.N.O.C. in the blood is 20 micrograms or more per gram. No antidote to D.N.O.C. is known. Early diagnosis is essential, and treatment on general lines will result in recovery, even in seriously poisoned patients. The patient must be kept cool by tepid sponging; fluids and electrolytes, which are lost in the profuse sweating that characterises the illness in its acute stages, must be replaced; barbiturates should be administered in doses adequate to allay the anxiety.

7. ANILINE

Aniline is a colourless, oily liquid which darkens on exposure to light or air. It is handled in the manufacture of dyes, in the dyeing and cloth-pressing industries, in the extraction of resin and in the rubber industry. Aniline poisoning arises usually from inhalation, but absorption through the skin and, less frequently, inhalation of dusts of aniline compounds may cause it. Care must be taken to change the clothes at once whenever they are splashed with aniline. Men must avoid entering chambers filled with its vapour. The symptoms of aniline poisoning are similar in all respects to those of nitrobenzene poisoning. The convenient term *anilism* may be used to cover the symptoms produced by most of the nitro- and amino-derivatives of benzene.

In *acute aniline poisoning* there is headache, weakness, difficulty in breathing, cyanosis, loss of power in the limbs and giddiness. In severe cases the cyanosis is more intense and prostration occurs with a cold moist skin, small pulse, air hunger and even death in coma. When recovery occurs it is often gradual and may be accompanied by increased frequency of micturition. In *chronic poisoning* the workers show slight cyanosis, secondary anæmia, and sometimes sleeplessness, headache, giddiness and abdominal discomfort. In hot weather practically all the men exposed to aniline and similar compounds in a dye works show cyanosis.

The manufacture of nitrobenzene, and the reduction of nitrobenzene and nitro-toluene to aniline and toluidine must take place in closed vessels. Even so, escape of small quantities of aniline into the atmosphere is very difficult to prevent unless ample ventilation is provided. Therefore, in addition to the technical regulations, there must be insistence on cleanliness of the workrooms, personal cleanliness on the part of the workers and provision of baths and changes of clothing. Contact with aniline and nitrobenzene, especially on the skin, and also the spilling and splashing

of these fluids must be carefully avoided. All workers must be instructed as to the symptoms of nitrobenzene and aniline poisoning, and the right steps to take if poisoned. Regular medical inspection of workmen is desirable.

Workers, and especially those newly employed, must be under supervision in order that assistance may be rendered them on the first signs of poisoning. Medical assistance should be within easy reach. Systematic instruction should be given in first-aid methods, and in the use of apparatus for oxygen and carbon dioxide inhalation. The possibility of skin absorption must always be borne in mind. A victim whose skin or clothing has been splashed with aniline may turn blue in the face and begin to stagger. Someone may take him out to the fresh air or administer oxygen, when what he needs most is to have his clothes stripped off and be given a bath. Workers entering stills and similar chambers should always be equipped with breathing apparatus and a supply of oxygen. Other aids, such as safety belts which are held by helpers, involve certain risks, especially as the rescuer is easily induced to spring to the assistance of his unfortunate mate without the necessary breathing equipment. The frequency of such accidents calls urgently for the use of breathing apparatus.

8. PHENYLENEDIAMINE

Phenylenediamine is used for two similar purposes; for dyeing hair black and as a dye for furs. It is well known that it may cause dermatitis and sometimes asthma in susceptible persons. Its systemic effects are much rarer and have received less attention. Hairdressers handling the dye have suffered from attacks of weakness and vomiting, with intense violet cyanosis of the lips and face. In unusually susceptible individuals toxic jaundice has occurred, followed by death from hepatic insufficiency after about 6 months. At necropsy the liver is small and shows the changes of sub-acute atrophy with regeneration nodules. Patch testing of the skin should be carried out on all applicants for the job of ladies' hairdresser; those showing a positive result must be rejected. Persons handling the dye should wear rubber gloves.

POISONING BY HALOGENATED HYDROCARBONS

The entrance of chlorine or bromine into an aliphatic compound increases its toxicity. This is less commonly true of an aromatic compound. The various members of this group are useful as refrigerants, as degreasers of metals, fire-extinguishers, cleansers of textiles, solvents for rubber and thinners of cellulose lacquers. Their usefulness is enhanced because they are non-inflammable, non-combustible and non-explosive. They vary greatly in their toxic effects, trichlorethylene being relatively harmless and tetrachlorethane deadly.

1. METHYL CHLORIDE

Men working in chemical plants or employed upon making, installing or repairing refrigerators may be exposed to methyl chloride. Symptoms of poisoning include giddiness, weakness of extremities, nausea, vomiting, restlessness, followed by somnolence and then by dimness of vision, which may not clear up until 14 days after removal from exposure. Later there is some rise of temperature, pulse and respiratory rate, usually with oliguria and occasionally with suppression lasting up to 48 hours. Evidence of acute nephritis is found in about half the cases. Anemia may be found, the red cells dropping as low as 3 million per c.mm., and the hæmoglobin as low as 50 per cent. The death-rate is as high as 35 per cent.

2 METHYL BROMIDE

Methyl bromide is a colourless, non inflammable gas, but it comes on the market compressed into containers in which it assumes the liquid condition. It is valuable as a methylating agent, a fire extinguisher, refrigerant, fumigant and insecticide. Methyl bromide is a deadly and insidious poison with a delayed action like phosgene and nitrogen dioxide. The latent interval varies from 4 to 48 hours, and then the patient is seized abruptly with nausea, vomiting, headache, vertigo, dimness of vision, diplopia, euphoria and delirium. In severe cases pulmonary oedema, oliguria, suppression of urine, convulsions and even acute mania may occur. The skin is pale, the temperature normal, sweating is profuse, trismus and even opisthotonus may be seen and the pupils are dilated. The skin may be affected in susceptible people, premonitory pruritus is characteristic and may be intense. Methyl bromide burns are superficial, rarely extending deeply enough to destroy the whole dermis. They are characterised by excessive vesication with reddening and swelling of the surrounding skin. Healing readily occurs and in most cases there is considerable desquamation. Mild cases usually recover, but where there is oedema of the lungs, convulsions, anuria or severe burns the outcome is often fatal. In cases showing mild systemic symptoms treatment by rest in bed for 2 days with 3 weeks' convalescence will usually be adequate. If there is cyanosis little can be done except to administer oxygen. The skin lesions should be treated with 2 per cent. tannic acid in triple dye solution or with propamidine isethionate cream.

3 CARBON TETRACHLORIDE

Carbon tetrachloride is used in industry as a solvent for fats and rubber, for dry cleaning for cleaning oil from machinery and under the name Pyrene as a fire extinguisher. Acute and sometimes fatal poisoning has occurred from the anæsthetic effects of carbon tetrachloride used as a dry shampoo for the hair. Men exposed to the vapour sprayed from Pyrene fire extinguishers in confined spaces have suffered from oliguria and jaundice. In animal experiments carbon tetrachloride has been shown to cause necrosis of the liver. In man it may give rise to acute nephritis, necrosis of the liver, oedema of the lungs or retrobulbar neuritis. The early stages of the illness are characterised by persistent headache, nausea, vomiting, diarrhoea and tenderness over the liver. Such symptoms are often followed by oliguria, suppression of urine and uræmia. Sometimes the clinical picture closely simulates that of the acute abdomen. The blood urea may rise to 300 mg per 100 ml and the patient, though practically moribund may suddenly develop polyuria and recover even after almost complete anuria lasting 10 days. When the liver is attacked recovery may follow an attack of jaundice lasting as long as 2 months. In the treatment of cases rendered unconscious by acute poisoning it is important that the patient should not be placed upon the floor of the room where the accident occurred for the vapour is five times denser than air and therefore accumulates on the floor. Hepatic insufficiency should be treated by glucose drinks, together with large doses of calcium lactate up to 15 g a day. Calcium gluconate may be given by intramuscular injection. Protein hydrolysates, methionine and vitamin supplements have also been used.

4 TETRACHLOROETHANE

Tetrachlorethane is the most dangerous of all the chlorinated hydrocarbons being nine times as toxic as carbon tetrachloride. It is a very good solvent for cellulose acetate, which being non inflammable, is used for purposes for which cellulose nitrate (celluloid) is not adapted. Cellulose acetate was the chief constituent of the dope used as a waterproof coating for the wings of aeroplanes in the War of 1914-1918.

and it is now used to make non-inflammable cinema film. The symptoms of poisoning are general malaise, loss of appetite, nausea, headache and constipation. After several days or even weeks, jaundice develops and vomiting is then likely to become more marked. In fatal cases necrosis of the liver is found in the form of acute red and yellow atrophy. In one case the liver weighed only 19 oz. The blood changes in mild poisoning consist of an increase of large mononuclear cells up to 40 per cent, with a slight elevation of the white count. Blood counts have been taken in order to detect early poisoning. Elaborate exhaust ventilation in factories and workshops fails to prevent toxic jaundice. It is therefore necessary to use a harmless substitute such as amyl acetate.

5 TRICHLORETHYLENE

Trichlorethylene is employed extensively in dry cleaning and as a degreasing agent. It has assumed an important place in the list of fat and rubber solvents, displacing to some extent carbon tetrachloride. Trichlorethylene has a powerful narcotic effect. The workman affected is usually found unconscious on the floor, and if there has been prolonged exposure to a large dose the effects may be fatal. Chronic exposure has been held responsible for paralysis of the sensory fibres of the fifth nerve, and also for retrobulbar neuritis followed by optic atrophy. An indirect form of injury to the eye sometimes occurs when a foreign body lodges in the cornea and produces ulceration. The workman is not aware of the presence of the irritant substance, because the cornea has been rendered insensitive. Trichlorethylene is not so likely to attack the liver as tetrachlorethane. Toxic jaundice and albuminuria have been recorded only rarely. Dry cleaning establishments employing trichlorethylene should be provided with efficient exhaust ventilation. When solutions containing trichlorethylene are applied to the interior of closed vats the men should work in pairs, relieving each other frequently. The man in the enclosed space should be provided with a lifebelt and also with an apparatus through which he can breathe air from outside.

6 CHLORINATED NAPHTHALENES

When naphthalene is chlorinated a series of wax like substances is produced. These are used as an insulating coat on wires or on metal bars to circumscribe the action of plating processes. They may produce acne, starting on the face and around the angles of the jaws and malar prominences, and spreading on to the sides of the face, neck, shoulders and forearms. The skin lesions in a typical case are comedones, papules, pustules and, in severe cases, small cysts. Since 1936 several cases of jaundice have occurred in workers handling chlorinated naphthalenes. In one fatal case necropsy showed acute red and yellow necrosis of the liver, which weighed 650 g, the normal being 1500 g. By attention to ventilation, protective clothing and medical supervision of workers, the chlorinated naphthalenes can be handled in industry with safety.

DECOMPRESSION SICKNESS

Synonyms—Caisson Disease, Compressed Air Illness, Divers' Paralysis, Aeroembolism of Aviators.

Definitions—Decompression sickness is the name given to the symptoms which appear (i) when workers in compressed air are too rapidly decompressed, (ii) when deep sea divers or men escaping from sunken submarines come too rapidly to the surface, and (iii) when airmen or air passengers ascend too rapidly to high altitude.

Ætiology—Caisson disease is an industrial hazard encountered in those processes of subaquatic engineering in which compressed air is employed. The work

of excavating for the foundations of piers, river bridges, skyscrapers and certain tunnels is carried out in a subaqueous chamber called a caisson. This is essentially a tube of iron or concrete open below and provided with a cutting edge by which it sinks when weighted into mud, sand or moist earth. The working chamber at the bottom is kept clear of water by compressed air, and it is here that the men work. Pressure is produced and maintained by pumps and regulating apparatus.

It follows that caisson workers are submitted to a pressure of air which just exceeds the hydrostatic pressure of that depth of water in which they work. Workmen descend to the working place of the caisson by passing from the normal atmosphere through a series of chambers with airtight doors in which the air pressure is raised by rapid stages until the high pressure of the working place is reached. They leave through the same chambers, the air pressure being lowered for some space of time in each as they pass through. This process is termed "compression" and "decompression", or "locking in and out". Caissons are usually worked at a pressure of below 35 lb and in 6 to 8 hour shifts, but they have been successfully worked at a pressure of 45 lb with 2 hour shifts, and at 50 lb with 1-hour shifts.

Divers are employed in the construction of harbours, docks, piers, breakwaters and bridges, in recovering sunken ships, cargo and treasure, in cleaning and repairing the hulls of ships and in fishing for pearls and sponges. The diving dress used consists of a copper helmet attached to a metal corselet the latter being secured water tight to a rubber suit fitting closely every part of the body except the hands which pass through elastic cuffs. The boots are heavily weighted. Compressed air is supplied by an air-pump on the surface through a flexible pipe and is carried through a tube at the back of the helmet. The exhaled air escapes through a spring valve at the side of the helmet whenever the inside pressure becomes slightly greater than that of the surrounding water. For every 33 ft ($5\frac{1}{2}$ fathoms) in depth of water the pressure increases by 1 atmosphere or 15 lb to a square inch. Thus the diver is compressed as he slowly descends by an increasing air pressure from his pump and is decompressed as he ascends much more slowly. Divers frequently work at 120 ft (53 lb), and the record depth has been 420 ft (182 lb) but to resist the pressure at such a depth an incompressible metal suit must be worn. The working shifts of divers are much shorter than those of caisson workers.

Decompression sickness of aviators differs from caisson disease only in its lesser severity. In flying, symptoms may develop at 32 000 ft if the rate of climb is 200 ft a minute or more. They may appear after a few minutes or only after 2 or 3 hours according to the particular susceptibility of the individual. Above 37,000 ft any reasonable rate of climb is very likely to produce symptoms even in the most resistant

distension from trapped gases in the intestinal tract. Nitrogen released in the tissues appears to act principally by causing pain in the unyielding tissues such as bone, tendon, fascia, periosteum and nerve sheath. Neural damage due to aeroembolism varies greatly, is non-specific, and unpredictable. That part of the nervous system which is least vascular, namely the four lower dorsal segments of the spinal cord, is the region most commonly affected. Hundreds of bubbles have been counted in the spinal cord and these are much more numerous in the white than in the grey matter. In every fatal case which has been adequately examined at necropsy patches of necrosis in the dorsal region of the spinal cord with the usual secondary degeneration have been found. Hæmorrhage is a relatively unimportant finding. Massive escape of nitrogen bubbles may occur into the blood-stream and, in rapidly fatal cases, the heart has been found distended with gas after death. Nitrogen bubbles in the pulmonary artery and its branches may cause death through occlusion of the circulation and asphyxia. Collections of nitrogen may be found in the subcutaneous tissues and may cause subcutaneous emphysema with palpable crackling. Nitrogen embolism may cause necrosis of the tissues in any part of the body.

Symptoms.—The actual ascent and descent of caisson workers, divers and airmen is associated with no worse symptoms than discomfort in the ears from disparity of air pressure in the middle ear ("car block"). Rupture of the tympanic membrane is rare and may be associated with infection of the middle ear—"aero-otitis media". If air under pressure is trapped in the nasal sinuses there may be pain ("sinus block"). Teeth showing subacute inflammation of the pulp may ache at high altitudes ("aerodontalgia").

The symptoms resulting from decompression will be severe in direct proportion to the length of exposure to an abnormal pressure and to the rapidity of return to atmospheric pressure. No symptoms occur after short exposures to compressed air such as 15 minutes at a pressure of 45 lb., or 2 minutes at a pressure of 75 lb., even though decompression be as rapid as possible, for these periods are too short to allow of nitrogen saturation of the tissues. It is for this reason that decompression sickness is less common in divers, who for the most part work for a short time only at high pressures, and so much more common in caisson workers who work for many hours at a stretch at a pressure of from 30 to 40 lb. Similarly, airmen usually remain above 30,000 ft. for too short a time to be affected.

In caisson workers the onset of symptoms is relatively rapid, in 60 per cent. during the first hour, in 35 per cent. during the second hour, in 3 per cent. during the third hour and in the remaining 2 per cent. after 12 hours. The commonest symptom is dull throbbing pain, gradual in onset, progressive and shifting in character, and frequently felt in the joints, or deeply in muscles and bones. Pains of this nature are referred to as "the bends", a term established by long usage and arising in the fact that the limb affected is held in a semi-flexed position from which it is found difficult to straighten it. The elbows, wrists, knees and hips are the areas most frequently affected, but the epigastric and lumbar regions may be involved too. Numbness may precede the onset of pain. Skin temperature may fall as the part involved becomes blanched in appearance. Erythema of the skin with pruritus ("the itch" or "prickles") occurs with regularity if the skin is chilled during decompression. A type of asphyxia known as "the chokes" or "the chokers" may occur, though it is less frequent than "the bends". Several hours of complete well-being following decompression may elapse before the appearance of the earliest symptom of "chokes", namely, a sensation of substernal distress felt only during deep inspiration which frequently serves to elicit the cough reflex. This sensation of substernal distress may be only transient or it may progress to frank asphyxia. Normal breathing becomes shallow, rapid and then dyspnoic. The skin becomes cyanotic, or ashen grey, cold and clammy. The pulse, at first slow and pounding, becomes thready. Paroxysmal attacks of coughing or true "chokes" may precede loss of consciousness.

The picture presented is one of "shock" and represents a transformation within a period usually of several hours from a state of health and vigour to one of incapacity without any apparent trauma being inflicted upon the individual. It is this condition which not only frequently supervenes in divers when the premonitory symptoms of "bends" are ignored and treatment delayed, but may also be responsible for circulatory collapse and deaths which occasionally occur following too rapid decompression in the low-pressure chamber.

Vertigo ("the staggers") is a common symptom. The staggering gait may be accompanied by nausea, vomiting, tinnitus and nystagmus. When paraplegia occurs it usually extends as high as the ninth dorsal segmental level, but may reach the cervical region and involve the arms. It comes on rapidly and involves motor, sensory and sphincter functions. It may be of any degree of severity from a slight and transient effect to a complete and permanent loss of the functions of the spinal cord. It occurs with increasing frequency and completeness in proportion to the degree of pressure and the length of exposure to its influence. Hemiplegia or monoplegia of cerebral origin are less commonly seen.

The complications of decompression sickness are limited to certain lesions of the lungs, bones and joints which occur in caisson workers. Spontaneous pneumothorax is a rare complication of too rapid decompression. Where bone complications occur, the symptoms of onset are insidious and are delayed from 6 months to a year or more following repeated attacks of caisson disease. Various infarcts, possibly due to nitrogen emboli in end arteries of nutrient vessels, lead to aseptic necrosis of areas of bone and sometimes of articular cartilage. The bones of the lower limbs are commonly affected and the joints include hip, knee and shoulder. Where the diaphysis of a bone is involved the lesion results in an encapsulated calcified area. The joint lesion may lead to persistent pain and ultimately to osteoarthritis with disablement.

Treatment.—**PROPHYLACTIC.**—The ideal age for compressed air workers and aviators is between 20 and 40 years, since during these years the cardio-vascular system is at its greatest efficiency and therefore best able to withstand the hardship involved. All persons with disease of the heart, lungs, kidneys and peripheral vessels should be rejected. Obese men are bad risks because fat deposits act as a gaseous reservoir predisposing to bubble formation. Acute infections of the respiratory passages must temporarily disqualify a man for employment because the infection may involve the Eustachian tubes and the ostia of the sinuses with the risk that air will be trapped in the middle ear or sinuses with consequent infection or rupture of the tympanum. The workman, airman or air passenger avoids the consequences of unequal pressure on either side of the tympanum by opening the Eustachian tubes

may not be associated with cyanosis. It is the usual result of breathing a rarefied atmosphere in which the partial pressure of oxygen is lowered, and in this connection is known as "mountain sickness" or "altitude sickness" when heights approaching 20,000 ft are reached. The characteristic phenomena can be produced at will by respiration within a partially exhausted chamber, and they can be obviated at high altitudes by adequate oxygen addition in respiration. Arterial anoxæmia is also present to some extent in those pulmonary diseases in which there is damage to the respiratory epithelium, obstruction to the air passages and when prolonged shallow breathing occurs, as in pulmonary œdema, emphysema and pneumonia, and in these conditions oxygen addition is valuable if its administration can be very prolonged.

2 *Stagnant or passive anoxæmia*—This results when, on account of some fault in the circulatory mechanism, the passage of the blood through the tissues is too slow to provide for adequate oxygenation. It is the common happening in the circulatory failure of cardiac disease. There is here no fault with the oxygen content of the arterial blood. The oxygen saturation of the venous blood falls lower than 65 per cent. of the normal, and the normal difference between the oxygen saturation of the arterial and of the venous blood, which is 20 to 30 per cent., is exceeded, and there is always cyanosis, which appears when the reduced hæmoglobin content reaches 40 per cent. of the total hæmoglobin. Since the arterial blood oxygen content is not at fault, oxygen administration is useless to relieve this condition.

3 *Anoxic anoxæmia*—This results from a deficiency in the oxygen-carrying power of the blood, either by reason of deficient hæmoglobin content, as in the anæmias, or by fixation of some of a normal hæmoglobin content, as methhæmoglobin, sulphemoglobin, or carbon monoxide hæmoglobin. In the anoxic varieties, cyanosis does not occur, however severe the anoxæmia, for the reason that cyanosis only appears when 40 per cent. of a normal hæmoglobin content exists as reduced hæmoglobin. Therefore, an anæmic patient with 50 per cent. hæmoglobin would require 90 per cent. of the total hæmoglobin present to be reduced for the appearance of cyanosis. Oxygen administration is of no avail in anoxic anoxæmia.

ALTITUDE SICKNESS, MOUNTAIN SICKNESS—There is considerable difference among individuals as regards liability to the appearance of symptoms at low atmospheric pressures, some suffering earlier and more than others. The immediate effect of exposure to such pressures is to cause rapid concentration of the blood and therefore a relative increase of the ratio of the hæmoglobin to the volume. A 10 per cent. rise in the hæmoglobin ratio may occur after 20 minutes' exposure. This is in part produced by the role of the spleen in acting as a reservoir for the erythrocytes, which are discharged rapidly into the general circulation under these circumstances. This serves as a compensation for the oxygen-want of the tissues, and its occurrence is associated with a disappearance or amelioration of the initial symptoms of oxygen-want. In those who remain at a bearable high altitude many weeks, some degree of acclimatisation occurs, and this is associated with hyperactivity of the blood-forming organs and an erythrocytosis. The anoxæmia produces hyperpnea, and there is at first an alkalosis from increased ventilation, which subsequently lessens.

Symptoms—*Mental effects* are most important when rapid ascents to high altitudes are made in aviation, and consist of a gradually increasing dulling of perception, of which the subject is usually unaware. There is an increasing inaccuracy and lethargy of mental functions, with a tendency to torpor and loss of memory. The skilled photographic observer takes many photographs upon the same plate, the observer throws his valuable notes overboard, the navigator makes for a wrong destination or goes to sleep, and the fighter pilot forgets to go into action. On return to land a muddled and confused memory of what has happened during the flight is all that remains. Lesser degrees of this condition have led to great errors in judgement, foolishness, apparent cowardice and irresponsibility in military aviation. So irrevocably does this mental paralysis come on and so deep may be its effect before

its presence is realised, that in Tissandier's balloon ascent in 1875, all three aeronauts, though provided with oxygen apparatus, were paralysed beyond movement before realising the necessity for using it, and two of them lost their lives. Diminution of auditory perception becomes so great at high altitudes that the aeroplane engine becomes almost inaudible.

Respiratory effects.—At an altitude of 12,000 ft., nose-breathing ceases, and above this height the breathing deepens into hyperpnœa, which is periodic and may be most distressing. The dyspnœa is greatly increased on exertion and is accompanied by cyanosis. Even such acts as talking and using a pressure pump may greatly increase the dyspnœa.

Muscular weakness.—Accompanying the mental lethargy is an increasing condition of muscular weakness. The slightest exertion is hard work. The machine is difficult to fly at very high altitudes, the marksman shoots badly and the mountaineer becomes incapable of taking exercise.

Other symptoms which may occur are—(1) headache, which may be very intense and which is usually met with in prolonged exposure to high altitudes, as in mountain climbing; (2) spasmodic gulping accompanying the hyperpnœa; (3) fainting on exertion; (4) increased frequency of micturition; and, rarely, (5) vomiting and (6) epistaxis.

The mental effects were most conspicuous in aviators who had to make prolonged flights at very high altitudes before the regular use of oxygen apparatus. The dyspnœa, headache and muscular effects have been most troublesome in mountain ascents where exertion is unavoidable.

Death has occurred in balloon ascents to gain a great altitude. It occurs very rapidly and is preceded by general muscular paralysis. Glaisher and Coxwell survived 29,000 ft. by a lucky chance after complete paralysis of the limbs had set in. Sivel and Croce-Spinelli died at a height of 27,500 ft., while Tissandier, who was with them, survived. Exposure of airmen to high altitudes produces the following effects: The gait of the men on landing is unsteady and laboured. Reports are laboriously made out (there being a general disagreement as to what was seen and done). Tempers are short, everyone looks and feels tired, and the idea uppermost in the mind is to lie down and go to sleep. Severe frontal headache is common; it may persist until the following day and at times proves incapacitating. Appetites are poor and spirits are depressed. A repetition of this kind of work over any length of time rapidly produces deterioration of mental and physical well-being.

Remarkable individual tolerance to anoxæmia occurs in some subjects, but this tolerance tends to disappear with repeated long exposure. Physical fitness and training increase tolerance up to a certain point, whereas unfitness and especially digestive disturbances lower tolerance, and the latter are apt to induce vomiting.

Treatment.—Since the symptoms are due solely to lack of oxygen they can be entirely avoided by the use of a portable apparatus to deliver the necessary oxygen by all those who have to encounter an altitude of over 15,000 ft. The essential feature of such an apparatus is the regulation of oxygen delivery by an aneroid controlled valve, so that the amount of oxygen delivered varies in inverse proportion to the barometric pressure of the atmospheres surrounding the instrument, and consequently, in direct proportion to the altitude.

When symptoms have developed, the immediate treatment requisite is the cessation of exertion, the provision of oxygen if available and a speedy return to a lower altitude.

TRAVEL SICKNESS

Under this heading can be included sea-sickness, air, train and car sickness. By far the most disabling form of travel sickness is sea-sickness. It is a disorder of

gastric and intestinal function brought on in susceptible subjects by travelling on the sea. A similar disorder occurs in many persons under various other conditions in which they are subjected to repetitive irregular motion as in an aeroplane, a swing, a roundabout and, to a less degree, in a railway train, a motor car, a lift or even during dancing.

Ætiology and Pathology—It is well known that irregular and unaccustomed stimulation of the labyrinth causes nausea and vomiting, and also other disorders of function in the structures innervated by the vagus or parasympathetic system. In travelling through rough seas the roll and pitch of the ship cause excessive stimulation of the labyrinth. In the case of car and aeroplane travel the labyrinth is subjected not only to the effects of rotation of the body through planes to which it is unaccustomed, but also to rapid accelerations and decelerations as well as to altitude changes. Another influence is the reception of irrelative impressions from the other afferent organs which subserve the orientation of the body in space and the appreciation of movement, namely, the eyes, and the postural sensory system of muscles and joints. Psychological factors, especially apprehension, also play a part. Train and car sickness are mainly concerned with the visual factor and are brought about by the difficulty experienced in adjusting vision to the rapidly passing landscape. A receding landscape imposes such disability on certain individuals travelling by train that they can only travel facing the engine.

The degree of susceptibility varies greatly in different individuals. Early infancy is immune from the affection, since the orienting mechanism has not attained full physiological activity, and old age is relatively immune, probably from lessening irritability of the nervous system. Individual hypersusceptibility and individual immunity are very common, and the readiness with which tolerance is acquired by training varies greatly in different people. Personal immunity is for the most, relative only, for there are few who can pass through excessive and prolonged stimulation without developing some of the characteristic symptoms. The development of tolerance by habitude varies greatly. Some develop tolerance readily, and others with great difficulty. Years of continuous sea going may pass before any tolerance is developed, and many sailors never acquire any, as was the case with Admiral Nelson. Of the many adjuvant factors the more important are apprehension, or the full expectation of being sick, the smell of the ship and especially of oil, heat, a stuffy

or other movement causing the condition is over, but sometimes dizziness, headache and gastric symptoms persist for a long time, and the patient is "good-for-nothing" until he has had a night's sleep. In persons taking long sea voyages, the symptoms usually lessen in a few days, reaction sets in, accompanied by a return of appetite, and convalescence is complete within a week, but symptoms are liable to return with an onset of rough seas. Some persons, on the other hand, never lose the symptoms until the voyage, however long, is over, and these may be reduced to a piteous condition of bodily weakness, from which subsequent convalescence is slow. Death appears rarely, if ever, to have occurred even in the most severe condition of bodily depression and starvation from sea-sickness alone. Apart from the long convalescence which may be required in severe and long-lasting cases, there seem to be no harmful results.

Treatment—Securing an airy cabin amidships with pleasant distractions during the voyage may prevent symptoms. Even unpleasant distractions such as fear and excitement in troops about to land on a hostile shore are often effective. Many drugs are valuable in the control of sea-sickness. They include hyoscine, diphenhydramine (Benadryl), dimenhydrinate (Dramamine), chlorcyclizine (Histanin), promethazine (Phenergan) and benzhexol (Artane). Their mode of action is not known, it may either be a direct sedative effect on the vomiting centre or a central anticholinergic effect. Not one of these drugs is outstanding, but hyoscine hydrobromide 1 mg taken an hour before sailing will prevent sickness during short sea journeys in the majority of susceptible people. On long voyages, taken in the effective dose of 0.75 mg t.i.d.s., it may cause unpleasant side-effects and promethazine (25 mg t.i.d.s.) is to be preferred.

ELECTRICAL INJURIES

Electrical injuries may be received from lightning stroke, from accidental contact with high tension conductors, on railways or in factories, mines and shipyards, from faulty household electrical appliances, or from judicial electrocution where this obtains.

Ætiology—In Great Britain electricity is usually supplied to householders at voltages under 250. The severity of the injuries sustained in any given case depends upon other factors than the voltage of the discharge received, and thus it is that fatal injuries may be received from currents of comparatively low voltage (120 volts), and survival may follow the reception of currents of higher potential. A current of 500 volts is commonly fatal, and alternating currents are usually more dangerous than direct. Voltages of over 1000 are spoken of as "high tension". The quantity of the current is also of importance. A current of 100 amperes is dangerous, one of 500 is likely to be fatal. The lightning flash is a rush of protons and electrons through the air in a path which may be more than a mile long and about 20 ft wide. The current is direct, not alternating, of the order of 1000 million volts and perhaps 20,000 amperes. The duration of a single stroke is about a thousandth of a second. In judicial electrocution the victim is subjected to repeated discharges (4 to 8), each lasting some seconds (5 to 50), of alternately low and high potential (500 and 2000 volts).

Pathology—In death from lightning stroke the head is invariably struck. The body surface shows burns of various forms. In the nervous system there are abnormal rents and fissures in the brain, the cerebrospinal spaces are distended, the perivascular spaces enlarged and the arteries at the base of the brain may show rupture of their muscular coats. In various situations the nerve cells show severe disruptive changes. The passage of the current through and over the body is inadequate to account for the lesions found in the nervous system. They are due to the charging of the body itself with electricity.

If a man makes contact with a conductor at high potential, or if he be struck by lightning, he will suddenly become highly charged with electricity. A current

will pass through him only if he is in a position to lose this charge. If he be earthed the charge will pass rapidly through and over him, and will not accumulate upon him. If he be more or less effectively insulated from earth, his body surface will become highly charged, and electrostatic forces will develop from the mechanical repulsion which is exerted between similarly charged particles or bodies. A charged body will be repelled from all similarly charged bodies, and all the constituent elements of the body which carry the charge will be repelled from one another.

Thus it is that when more than one object is struck by lightning, they are flung apart; a man is flung several yards from a tree under which he has been standing; or two men simultaneously struck are flung away from each other; a parcel held by an individual struck is hurled out of his grasp, and also his clothes, belt and boots are burst and torn off him in fragments, and he may be stripped naked. Within his body the same disruptive forces are at work, and produce lesions in proportion to the rigidity and cohesion of the tissues. This accounts for the characteristic disruptive lesions found in the brain. In addition to these mechanical effects the current also produces heating and electrolytic effects but these are probably negligible as far as the morbid anatomy is concerned.

Symptoms.—The effects of lightning-stroke include burns, lacerations, fractures, conjunctivitis, paresis of accommodation, cataract, partial alopecia, flaccid paralysis of the lower limbs and hysteria. Of all these lesions the burn is the most common. It may occur in an unusual pattern as an arborescent marking ("brushburn"), or a series of long narrow lines on the skin. It is not a true burn for it is painless and without inflammatory reaction. Metal objects in the pockets or in contact with the body such as buckets and iron rods, may determine the site and severity of the lesions.

A person struck by lightning usually falls unconscious at once. Retrograde amnesia is common. Sometimes he speaks of having received a tremendous blow on the head, or of intense visual or auditory sensations, of pain in the trunk and limbs, or of giddiness. The subject is unconscious, pale and pulseless, and respiratory movements are suspended. This initial state of suspended animation or apparent death is common after lightning-stroke, but not so frequent after accidental electrical injuries from contact with conductors. There may be powerful and generalised muscular spasm for a brief period and the limbs may be in flexion. It is because of similar spasm in the heart and muscular arteries that the victim is pulseless and pale. Surface burns of varying severity are seen, and examination of the scalp will reveal a localised swelling at or near the vertex, with no cutaneous abrasion. . . .

the current can be switched off quickly death may result, but the degree of electrocution varies considerably according to the degree to which the patient is insulated. If the current is switched off within a few minutes the patient usually recovers consciousness quickly, but suffers from a variable degree of shock and muscular spasm.

In another group of cases persons are electrocuted whilst taking a bath. An individual standing or sitting in a bath may pick up an electric hair-dryer or touch an electric heater, probably with a dripping hand. Instantly electricity passes over the patient's wet body, and the water and the bath become charged with it. The symptoms which ensue in the occupant are those already described, and unless the contact is broken, death may follow rapidly.

Diagnosis.—Where death has occurred from lightning-stroke, the following signs are found. There is an effusion beneath the scalp without superficial abrasion, and streaks of "brushburn" will be found upon the skin. The body will be more or less stripped of clothes. If a hat was worn, a hole will probably be found in it over the site of the scalp lesion. Leather garments, boots and belts are burst. Of course, if the victim was hurled or flung down some other signs of injury caused in this way may be found.

Prognosis.—Following lightning-stroke the number of deaths is small in proportion to minor injuries; out of 300 persons in a church which was struck, 100 were made unconscious and injured, 30 had to take to bed and only 6 were killed. Recovery from the average burn, laceration and fracture is prompt. Conjunctivitis and paresis of accommodation rapidly disappear. Flaccid paralysis of the lower trunk and limbs is temporary, power and sensation usually returning to normal after 12 hours. In cases of alopecia the hair grows again after 6 months. Hysterical deafness, blindness and aphonia should recover with adequate treatment. The only lesions which ever remain permanent are both rare, namely, cataract and a condition called spinal atrophic paralysis. This consists in muscular atrophy with fibrillation without sensory disturbance, in the distribution of the fourth to sixth cervical segments of the cord. It may progress and cripple the patient.

Treatment.—**PROPHYLACTIC.**—Thunderstorms are less common in high latitudes than nearer the equator. On mountains and in open country, especially in the tropics, it is important to know what to do when lightning comes near. It is safest to be inside a house, in a room with all the doors and windows closed, and away from the fireplace. In Great Britain telephones are fitted with lightning arresters and so may be used without danger. If there is no house, shed, cave or closed motor-car available the protection of a ditch or hollow should be sought. Crowds of people and the neighbourhood of domestic stock should be avoided, as should trees standing alone, wire fences, hedges, walls and the banks of rivers and ponds. The centre of a wood is fairly safe. If one has to be struck it is better to be wet through, for wet clothing may short-circuit most of the current.

In factories, mines and shipyards safety must be secured by the proper design of electrical apparatus, an active inspectorate and adequate safety-first propaganda. The generators, transformers, motors and switchboards should be placed on a floor itself made of some insulating material and covered with insulating mats which must be kept dry and free from oil. No circuit should be worked upon until the power has been cut off and the switch padlocked. If it becomes absolutely necessary to handle a live circuit, care should be taken to work upon but one wire at a time and to wear rubber gloves.

Pylons carrying live wires must be provided with danger notices and fitted with metal spikes to discourage attempts to climb them. Where roads cross electric railways fitted with overhead conductor wires, screens must be erected in such a way as to prevent the electrocution through the stream of urine of small boys who engage in the ingenious but deadly pastime of aiming at the wires in this particular way from the bridges. In the home, bathrooms must never be fitted with electric power

points because of the danger involved in touching a defective electrical appliance with wet hands while standing in water in a metal bath.

CURATIVE.—When the victim is unconscious, white and pulseless, artificial respiration must be undertaken at once, and persevered with for at least 8 hours before abandoning the patient. In factories the majority of recoveries when artificial respiration is applied occur in the first 10 minutes, a good proportion in the second 10 minutes but fewer after this period. There are few records of artificial respiration having been carried on in fatal cases for much longer than an hour, while many attempts are abandoned within half that time. Swallowing is the most reliable sign of the return of spontaneous breathing. Even when respiration is first resumed, it may fail again and artificial respiration must be kept up until normal breathing movements are fully established. The usual restorative measures employed in severe shock must also be used. When consciousness is regained, the patient may complain of severe headache and of painful muscular cramp. The latter should be treated by massage.

The superficial linear burns of lightning-stroke are best covered by aseptic dressings, when they usually heal without scarring. The deeper burns related to metallic objects carried by the victim, or to the points of entry and departure of the current in accidental injuries from contact with conductors, will require the ordinary treatment of burns according to their depth and extent. Neurological symptoms and disabilities have to be dealt with according to their character and severity.

THE EFFECTS OF HEAT

Under this heading are included those important conditions which result from exposure to high temperature. They are (1) heat exhaustion; (2) heat cramps and (3) heat hyperpyrexia (heat-stroke, sun-stroke, heat retention).

Ætiology.—The factors which lead to these affections are divided into the environmental and the individual.

Exposure to heat is the environmental necessity. Naturally, cases are most common in the tropics where there is danger in any shade temperature above 110° F., though heat exhaustion is not rare on a hot English summer day. There is, however, no special quality of solar rays to blame, for in experimental work direct exposure of the head to the sun is well tolerated if other factors are favourable, while heat-stroke is common in the gloom of a ship's stoke-hold. Those who live well exposed to the sun at high altitudes do not suffer like those on the plains. In tropical campaigns the rise in case incidence appears to lag behind the rise of atmospheric temperature by a few days. In individual instances illness follows exposure by some hours, suggesting some cumulative effect.

Furnacemen, foundrymen, forge hammer workers, ships' firemen, iron and glass workers, and miners in deep mines run the risk of undue exposure to heat, and it is in these men that heat cramps are to be expected. In tropical countries, laden troops on the march readily succumb to heat-stroke.

Climate, atmosphere and, in particular, humidity must be considered. A heat wave in any country leaves its quota of cases: in deserts without shade, and countries where day and night temperatures are both high, there is more danger. Most important of all, an atmosphere with a high humidity hinders heat loss from the body, and in motionless air where the wet-bulb thermometer reads 83° F. there is considerable chance of heat-stroke; still and poorly ventilated atmospheres themselves predispose to it, and the value of fans is self-evident.

Dwellings must be made of thick non-conducting material if they are to be protective, and in this respect a tent is of little use. Buildings should be well ventilated, and it has become almost instinctive for people in tropical climates to open their windows only in the cooler parts of the day.

Clothing needs to be light and loose fitting, experienced workers in hot damp places have found that they are more comfortable if they wear a cotton shirt than if they are stripped to the waist and bathed in sweat

Deficiency of salt in the body is just as important as any of the above factors and is thought to be the basis of all conditions attributable to heat. Sweat contains about 0.25 per cent of sodium chloride, and by sweating a man may lose as much as 30 g of salt in a day. In the absence of added salt, such a depletion may predispose to heat stroke, and is certainly the principal cause of heat cramps. This fact was discovered by J. S. Haldane in the deep South Staffordshire coal mines. He was the first to suggest that the cramps would follow the drinking of water, but that they could be avoided if salt were added to the water. Directly linked with sweating is the amount of exertion undergone so that heavy work in a hot and unfavourable atmosphere is particularly dangerous.

Predisposing factors include malaria, fatigue, alcoholism, metabolic diseases, gastro intestinal disorders in which water and salt are readily lost and the previous use of strong purgatives, thyroid or atropine. Native races are usually immune unless there is other disease present, old people are susceptible, so are those who have previously been affected. Some people have a constitutional inability to perspire. What is especially noteworthy is that an unacclimatised man is more susceptible than a veteran, for, during acclimatisation there is physiological conservation of salt and the salt content of the sweat falls to 0.09 per cent.

Pathology—In heat exhaustion a direct heat action upon the brain probably occurs in addition to the salt loss and the picture is akin to that of surgical shock. In heat cramps there is loss of salt and the serum sodium is lowered. It may be that the corresponding ionic changes at the myoneural junctions initiate the cramps particularly as the muscles most in use are affected.

In heat hyperpyrexia there is derangement of the heat regulating centre but salt depletion is also important, for the urinary chloride figure is very low. There is some evidence of increased metabolism in addition to indicanuria. That experimental hyperpyrexia can be induced with *beta* tetra hydro naphthylamine has been used in evidence to support a theory of auto intoxication by katabolites as the basis of heat stroke.

After heat hyperpyrexia rigor mortis occurs early and so do putrefactive changes. Oedema and hyperemia of the brain and lepto meninges occur, and the nerve cells in the grey matter show degenerative changes. In severe cases petechiae occur in the skin and mucous membranes and venous congestion is present in all organs.

1 HEAT EXHAUSTION

Acute symptoms may overtake a man at his work. There is an attack that suggests syncope, he becomes weak and faint, pale and prostrated, giddy and sweating. The pulse is weak and rapid, the blood pressure very low and the signs resemble those of shock. He may become unconscious. The temperature is normal or subnormal, respirations shallow and sighing and the pupils dilated. Recovery may be quite rapid but there is danger of hyperpyrexia later if the patient is not carefully treated for some days.

Treatment—Lay the patient on his back in a cool place, loosen the clothing and apply massage or local heat to the limbs. A warm bath may do good, give saline drinks, perhaps intravenous saline, and keep him under observation.

2 HEAT CRAMPS (See p 416)

In the second half of his shift at work a man may be seized with violent cramps. He is often of poor physique. The symptoms are more likely to occur should he have

been drinking water in quantity after a bout of sweating. The cramps are agonising, starting usually in the calves, moving later to the arms and abdomen, and he may appear knotted up in an attitude of flexion with contorted muscles. There may be intestinal colic and vomiting, for visceral muscle is not immune. In severe attacks it may take half a dozen men to hold down the sufferer, and afterwards he may say he would rather die than endure another attack.

Treatment—Prophylaxis is important. Those who work in conditions predisposing to heat cramps may have taken to shell fish, bacon, kippers, milk and even salted beer. Extra salt is needed, and this is provided by effervescent tablets containing gr 5 of sodium chloride flavoured with lemon. The men will relish a daily salt intake which would be nauseating to others. The usual requirement above a normal day's intake is about 15 g and double this amount in the uninitiated. For the attack, morphine may be necessary and sometimes intravenous saline.

3 HEAT HYPERPYREXIA

This is the most serious effect of heat. It may occur suddenly and proceed to coma and convulsions, but more commonly it begins gradually with irritable, querulous behaviour, malaise and headache, and the warning symptoms of polyuria, dryness of the skin, drowsiness, intolerance of light, tingling and cramps in the limbs, and a temperature of 100° to 102° F. This may last up to 48 hours, if by then the patient is not treated, there is a sudden rise of temperature to 110° F or more, the pulse becomes rapid and irregular, and there is mental excitement and delirium progressing to coma and convulsions. Now the face is flushed, the conjunctivæ congested, the pupils dilated, becoming constricted later, and the breathing stertorous. There may be albumin and indican in the urine, and in some cases ketone bodies. When coma is reached death follows quickly, sometimes with acute heart failure and œdema of the lungs. After recovery, residual dysarthria, ocular and other neurological signs may be seen, the temperature may stay at 102° to 103° F for days, and even when it has subsided the patient may be left for a long time susceptible to a recurrence of hyperpyrexia, he may suffer headaches and be unable to sweat. Variations of the clinical picture have been described in which the symptoms are predominantly gastric for 4 to 10 days when hyperpyrexia suddenly follows, or in which the main features are diarrhoea and vomiting.

Differential Diagnosis—Heat hyperpyrexia may resemble the cerebral form of malaria, or may follow directly upon any other serious physical illness. In malarial districts the coexistence of this disease should be presumed even if the blood films are negative. In pontine hæmorrhage there is also hyperpyrexia, but it is a late sign. A quantitative estimation of urinary chlorides is valuable evidence of heat hyperpyrexia if it gives a value below 3 g in a 24 hours' specimen.

Treatment—**PROPHYLACTIC**—In unfavourable climatic conditions special care must be taken and physical exertion restricted to the morning and evening. Men must have washing facilities, adequate sleep, plenty of salt in their diet and ample water to drink, but they should not take alcohol in the heat of the day. Extra sodium chloride should be given in doses of gr 10 to a pint of drinking water. In exceptionally hot weather hospitals should have wet screens and fans, anaesthetics and operations should be as few as possible, and care exercised in the use of such drugs as atropine.

CURATIVE—When any possibility of malaria exists full doses of quinine are needed at once. The temperature should be reduced and every step taken to increase heat loss by evaporation, as this is more effective than cooling by application of ice. The patient is placed on a bedstead on a porous mattress with free circulation of air all round and below him. If these facilities are not to hand, or if the humidity is very high, he may be put into a bath of cold or iced water up to the neck and massaged

vigorously When the temperature is being rapidly reduced by any means, rectal temperature readings every minute are necessary, and the process must be stopped at 103° F Then the patient is wrapped up and ice packs applied to his head and neck Rectal injections of iced water are only of limited value Rubbing with ice merely causes vasoconstriction, and delays the cure

The salt depletion is made up by drinks or rectal administration of normal saline, or, except when there is heart failure or convulsions, by intravenous saline Extra salt is needed for some days Heart failure itself is combated by a venesection of 10 to 20 oz Any stimulant which might induce convulsions is contraindicated Since the convulsions are due to cerebral oedema venesection is of value Withdrawal of cerebrospinal fluid by lumbar puncture is more effective than the use of hypertonic rectal solutions sometimes an anæsthetic is needed

The immediate danger past, the patient must be watched carefully in a quiet room for 3 weeks Bromides or barbiturates may be needed He should then be sent to a healthier atmosphere and must avoid any possibility of another attack for months afterwards

INJURIES FROM X-RAYS

Ætiology—Within 3 months of the announcement by Röntgen of his discovery of X-rays in November 1895, it became known that conjunctivitis could occur after some hours of exposure to irradiation A year later erythema, swelling and necrosis of the skin, alopecia and chronic radio dermatitis were reported In 1897 attention was directed to the acute constitutional symptoms In 1902 a case of cancer was recorded following chronic ulceration caused by X rays The first death recognised as due to the action of X rays occurred in 1914 In 1922 it was estimated that 100 radiologists had died from malignant disease due to their occupation Deaths occurred among radiologists exposed to X rays before the importance of adequate protection was realised, and unfortunately still occur

So far nearly all the victims have been research workers, radiologists, laboratory assistants, technicians and nurses Cases of industrial origin did not occur until later, because the use of X-rays in industry began later Industrial workers, unlike professional workers, are often quite ignorant of the possible dangers of the apparatus used, so that industry is now, in respect to the use of radioactive substances, about where medical practice was in 1914 There is, however, no reason why the lamentable history of the pioneers in the medical field should be repeated The human experiments have been made, the tragic results of carelessness demonstrated and the measures necessary for adequate protection are known and available to anyone who cares to learn them

X rays may be used in industry for the detection of defects, cracks and blow-holes in castings, of defects in alloys from faulty mixture, of erosion in cables or gas cylinders and of defects in reinforced concrete or in weldings X-rays are also used to sort fresh eggs from stale, to reveal mineral adulterants in vegetable foods and weevils in grain For the examination of metals and all thick objects very penetrating rays must be used

Symptoms—Injuries which follow a short single exposure, or perhaps several exposures, may vary enormously in intensity In mild cases there is simply a transient reddening, lasting a few days and followed by scaling and loss of hair If the burn is deeper, blisters appear which may be serous or purulent, and the condition resembles that following a scald but is less acute and slower to heal Sometimes the process, instead of disappearing in a few weeks penetrates to the deeper layers of the skin and to the subcutaneous tissues, with the formation of a leathery slough, surrounded by a brawny indurated swelling with ill-defined limits The process is exceedingly

slow and obstinate, and has a tendency to progress and to resist treatment in a remarkable way. It is at times very painful.

In chronic X-ray dermatitis the changes in the hands begin round the base of the nails as a peculiar erythema and gradually increase. Transverse and longitudinal ridges appear on the nails, which become brittle, assume a characteristic dirty brown appearance, tend to separate from the matrix and eventually thicken and form shapeless masses. The skin becomes uniformly red and atrophied, small warts appear, increase in size and number, and, when situated over the knuckles, crack and cause much pain. Later the dry thickened skin shows telangiectases, absence of hair, paronychia and ulcers which are slow to heal and prone to break down. The hair follicles and the sebaceous and sweat glands completely disappear in cases of long standing. The freedom of the palms of the hands may be due to the naturally thicker skin there, but the greater liability to exposure of the backs of the hands and fingers is probably the more important factor. The lesions are, as a rule, slowly progressive. Post irradiation telangiectases, which have been regarded as compensatory for obliteration of the vessels in the corium, usually appear within 2 years and sometimes in the absence of an initial erythema, in some instances the interval between irradiation and the appearance of telangiectases is prolonged, even to 15 years. If exposure is continued the lesions may progress to involve the tendon sheaths and joints. There may be intense pain, of which the severity is out of proportion to the size of the lesions, it is caused by the exposure of nerve endings.

Squamous celled carcinoma is almost always the form of malignant disease which has followed excessive X-ray exposure and long continued X-ray dermatitis in man. Although most often seen in radiologists and manufacturers of X-ray apparatus, X-ray carcinoma may also occur in patients who have undergone treatment by X-irradiation. The interval between the onset of chronic X-ray dermatitis and the appearance of malignant disease varies from 3 to 27 years. The average of 35 cases was 7 years. The age incidence from 35 to 50 is comparatively early, that of ordinary carcinoma of the skin being between 55 and 58. The most frequent site of the growth, which is not uncommonly multiple, is on the backs of the hands and fingers, and the hand more exposed appears to be the one more severely affected, the left in radiologists and the right in those engaged in the manufacture of apparatus. Among radiologists carcinoma usually develops in an ulcer, less often in keratotic areas. The predominating symptom is pain which may be constant and very severe, and has been ascribed to invasion of the terminations of nerves by the growth and to neuritis. Occasionally basal celled carcinoma results from X-irradiation. In one case a basal celled carcinoma of the scalp appeared 18 years after epilation for ringworm. A case has also been recorded of multiple basal celled carcinomas on the trunk of a radiographer.

Constitutional symptoms only became prominent after the introduction of deep X-ray therapy, in which massive doses of deep penetrating rays were given. Severe constitutional symptoms may occur. They are nausea, uncontrollable vomiting sometimes with hæmatemesis diarrhoea, with the passage of blood, abdominal pain and distension, fever up to 104° F., restlessness, profound prostration, progressive cardiac failure, small rapid pulse and dyspnoea. When death has occurred it has usually taken place about the fourth day from the onset. Both animal experiments and necropsies of human victims show that the application of X-rays to the abdomen may result in necrosis of the intestinal mucosa. As long ago as 1905 unsuspected sterility was found in 18 persons who had for various periods been exposed to X-rays. The acute degenerative changes in the testes are followed by fibrous atrophy. Anaemia occurs in X-ray workers. After small doses of X-rays, the lymphocytes are first increased in number then diminished. The red cells may also be increased at first, but anaemia sets in later and may become extreme. In patients who recover, the anaemia is slower to disappear than is the leucopenia. True aplastic anaemia does not occur.

Diagnosis.—The possibility of exposure to radium should always be excluded before attributing what appears to be aplastic anaemia in an X-ray worker to X-irradiation

Treatment.—**PROPHYLACTIC**—Within the first few months after their discovery it was found that X-rays were stopped more effectively by lead than by any other common metal. Hence lead for protection came into use very early. To-day lead, lead glass, lead rubber and lead bakelite are extensively used. Transparent lead glass windows in tube containers were first employed about 1900. At that time the need for protecting both operator and patient during X-ray exposure was very great, because low voltages were used, with consequent long exposure to a very soft and easily absorbed radiation. For example, to radiograph the spine required exposures up to 1 hour. That the radiologist was not more frequently affected by the scattered radiation of such exposures was due to the fact that during them he might retire to another room to see other patients. About 1903 there appeared a multitude of protective devices to be worn by the radiologist, including apron, jacket, gloves and goggles. This type of protection gradually reached its peak about 1914, when necessity threw caution to the winds, and the more elaborate devices gave place to means of protection which were built into the apparatus.

To-day there is international agreement as to the most effective methods of prevention. In Great Britain such methods have been widely adopted, and although they have no strictly legal recognition, powers of inspection and approval have been placed in the hands of the National Physical Laboratory. A service has been organised whereby the radiation received by a worker can be assessed by means of the blackening of a small wrapped photographic film worn on the coat lapel during working hours for a week. If the film, when developed, indicates a higher dose than 0.3 r per week the laboratory immediately follows up with an inspection of the department concerned. The results of film tests carried out on several thousand radiological workers from 1943 to 1948 indicated that about 80 per cent received less than 0.1 r per week from external sources of radiation. Repeated periodical blood counts must be carried out in all doctors, nurses, research workers, students, technicians and workshop employees exposed to X-rays.

It is important that the industrial physician should plan measures for the protection of employees against the dangers of X-irradiation, for in large manufacturing establishments there are X-ray departments for diagnosis as extensive and as much used as the average hospital department. Here the problem may include protection of workers in neighbouring rooms, for unless walls and floors are very thick or are rendered impermeable by the use of lead or barium concrete, X-rays may pass through them and cause injury.

SYMPTOMATIC—X-ray carcinoma should be treated by radical excision when this is possible, such as amputation of a finger, by diathermic coagulation under local anaesthesia, or by radium. Slight degrees of anaemia recover on removal from exposure. In more severe degrees iron must be used, and when this fails blood transfusion is necessary.

INJURIES FROM RADIOACTIVE SUBSTANCES

Aetiology—The gamma rays of radium appear to have a greater tendency than X-rays to cause aplastic anaemia, this impression is supported by the experimental evidence that the penetrative gamma rays of radium reach the bone marrow more readily than do X-rays. Three fatal cases of aplastic anaemia were reported in the London Radium Institute in 1920, one in a nurse and two in laboratory assistants. The late effects of internally deposited radioactive materials in man were studied from 1925 onwards. Paints consisting of crystalline phosphorescent zinc

sulphide, rendered permanently lustrous by the addition of a very small proportion of insoluble sulphate of radium, mesothorium and radiothorium, came into use about 1908. Such paints are applied to the figures of clocks and watches, and certain important parts of the machinery of aeroplanes. At two factories, one in New Jersey and the other in Connecticut, 38 deaths occurred among factory girls, chemists and physicists. The girls affected introduced the paint into their mouths through the habit of pointing the brush between their lips and swallowed it for periods of from 1 to 4 or more years. The insoluble radioactive materials became deposited in the body to such an extent that even during life radioactive emanations could be detected in the expired air. Pointing the brush with the lips was prohibited in 1924.

Pathology.—After death, bone was found to be the tissue in which the materials had mainly accumulated. Aplastic anaemia resulted from the continuous bombardment of the haematogenous marrow by alpha particles, and it was found that these changes were quite different from those due to external irradiation with beta and gamma rays only. Radioactivity in the bones and teeth was demonstrated by autoradiography. The bones when placed directly on photographic plates produced impressions in as short a period as 3 days. By 1952 there had been 14 deaths from sarcoma of bone which had appeared on an average 23 years after cessation of exposure to the luminous paint. In 3 cases deaths occurred from carcinoma of the paranasal sinuses, one of them 34 years after removal from exposure. The total amount of radioactive material necessary to produce fatal results is extremely small. It is sufficient for 0.01 mg. to be distributed over the whole skeleton to produce a terrible death years after it has been ingested. Radium is thus the most deadly poison known, tetanus toxin previously held the record with a lethal dose of 0.22 mg.

It is dangerous to use injections of thorium compounds for diagnostic or other purposes. Thorotrast, a thorium dioxide sol, was used for diagnostic radiography in doses which were carcinogenic. The alpha ray activity of 25 ml. of thorotrast has been found equivalent to a maximum of 1 microgram and a minimum of 0.5 microgram of radium. Thorotrast has been employed in hepatolienography, retrograde pyelography and arteriography, its elimination from the body is insignificant. In the diagnostic procedures mentioned it may be retained indefinitely in the liver, renal pelvis or subarachnoid space. By 1953, 7 deaths from its use had been recorded either from aplastic anaemia or from malignant neoplasms found to contain thorium concentrated in their substance.

Symptoms.—Dermatitis due to radium, isolated by the Curies in 1898, was reported in October 1900. Insufficiently protected tubes of radium salts kept in the waistcoat pocket for 6 hours produced reddening of the skin and within 10 days or so ulceration. Dermatitis has been reported in a number of persons engaged in making radium preparations and less often in medical men. The ill effects of ingestion of radioactive substances include severe anaemia, sometimes aplastic, necrosis of the jaw, spontaneous fractures, sarcoma of bone and carcinoma of the paranasal sinuses. The changes in the blood have been referred to as *anaemia radiotoxica*. The red cell count may drop below one million and the haemoglobin below 20 per cent. Leucopenia, granulocytopenia and thrombocytopenia all occur. Purpura is followed by more serious bleeding, such as menorrhagia, haemoptysis, haematuria and retinal haemorrhages. Necrosis of the jaw occurs. It is similar to that produced by phosphorus and is attributed to infection supervening upon changes in the bone. In certain cases necrosis of the jaw does not occur, but after a number of years generalised changes in the bones develop with deformity and sometimes spontaneous fracture, a condition known as *radiation osteitis*. Bone sarcoma occurs in 25 per cent. of the cases of occupational mesothorium and radium poisoning.

Treatment.—PROHYLACTIC.—Though medical practice is now almost safe so far as X-irradiation is concerned, matters are very different in the case of radium. There is no doubt that many people are affected by handling radium, chiefly by the

gamma rays. Their penetrative powers are so great that it is not practicable to secure complete protection. In the case of persons who carry radium about, the weight of lead they can bear to carry only partly protects them. Surgeons handling radium are also ill-protected. In the case of a man using 120 mg. of radium in the treatment of carcinoma of the cervix uteri, protection is very difficult as each time he has to handle the substance closely and carefully. In such circumstances the best protection is to keep the radium at as great a distance away as possible until it must actually be handled. It is obvious that ingestion or inhalation of radioactive materials in industry is highly dangerous, and that all occupations involving the handling of such substances should be strictly controlled and supervised. In the watch industry, outside New Jersey and Connecticut, the practice of pointing the brush with the lips is unknown, and no ill effects have been observed in other countries. In the luminous dial painting industry safety measures fall into two groups. First, there are precautions designed to reduce unavoidable exposure to a minimum and to improve the general conditions of work. These include protective gowns, rubber gloves and aprons, lead glass screens in front of the operatives and local exhaust ventilation. Secondly, examination of the operatives for over-exposure is necessary. In routine blood examinations, leucopenia, granulocytopenia or thrombocytopenia call for a change of occupation in the worker concerned. The hands must be repeatedly inspected for dermatitis. Workers must wear beta- and gamma-ray sensitive photographic films, and the radon appearing in the expired air must be repeatedly measured.

SYMPTOMATIC.—Like lead, radium has been shown to be stored largely in the bones. A course of treatment with calcium versenate (p. 371) may prove successful in reducing the amount of retained radium as indicated by the amount of radon in the expired air. For aplastic anæmia repeated blood transfusions will be necessary.

INJURIES FROM FISSION PRODUCTS

Fission of the uranium nucleus has led to an industry concerned primarily with the development of bombs. The stable and radioactive isotopes are essentially by-products of work on atomic energy, but they are assuming increasing importance in research, therapeutics and industrial processes, and radiation hazards in peace-time are therefore not confined to establishments concerned with atomic energy research and production. Ionisation may be produced directly by charged particles such as electrons or protons, or indirectly by the passage of uncharged neutrons, which cause ionisation by collision with some of the atoms of the tissues.

Dangers of exposure.—Danger may arise from direct radiation or from the inhalation or ingestion of radioactive materials. Neutrons and gamma rays are exceedingly penetrating, alpha particles can be stopped by a sheet of tin foil and beta particles by a tenth of an inch of aluminium. Alpha and beta particles when taken into the body can cause an immense amount of damage although absorbed in a comparatively small thickness of tissue. Radioactive substances which are particularly dangerous are those which are selectively retained in the skeleton. Thus uranium, thorium, plutonium and the isotopes of strontium and yttrium are bone seeking. Since some of these elements are excreted very slowly they will irradiate both bone and bone marrow continuously for many years.

Pathology.—The essential effect of irradiation is cellular injury leading to tissue necrosis. The erythron, lymphoid tissues and immature germ cells are the most sensitive, and highly differentiated tissues such as bone, nerve and muscle are less severely affected. Hæmorrhage results from vascular injury, thrombocytopenia and possibly from the presence of an anticoagulant substance in the blood. Secondary infection with ulceration of the gut and urinary tract and acute hæmorrhagic necrotising pneumonia are common. Sterility may be temporary or permanent and radiation

cataract may appear years after exposure. Little is yet known as to the carcinogenic and mutagenic effects of ionising radiations. Contamination of residential areas by radioactive dusts might cause cancer, and the bone-seeking isotopes would constitute a special long-term hazard. An increased incidence of hereditary defects in future generations is also a danger.

Effects of atomic warfare.—The most destructive effects of an atomic explosion are due to blast and to the release of thermal radiation. Casualties from blast, flash burns, debris and fire comprised 85 per cent. of the deaths at Nagasaki and Hiroshima. Ionising radiation arises in several ways during the explosion and includes neutrons, gamma rays and beta rays. A small proportion of the energy of the explosion appears as fast neutron radiation, which has great penetrating power but which rapidly loses its energy in traversing matter. It is of secondary importance to the gamma radiation which is also highly penetrating. Beta rays come to rest completely after passing through a few yards of air. When an atomic bomb explodes high in the air fission products are dispersed and contamination does not occur unless they are carried down by rain. In ground or underwater explosions there is a risk of direct exposure, ingestion and inhalation. The risk diminishes rapidly during the first 24 hours and its total duration depends on the prevailing weather conditions, the half-lives of fission products and other complex factors.

Symptoms.—In atomic warfare casualties can be divided, according to the degree of severity, into four groups, but the clinical picture in all the victims may be complicated by the effects of burns and other injuries.

Group I. Following exposure to intense radiation, nausea, vomiting and shock occur within a few hours and there is progressive weight loss, fever and diarrhoea leading to death from toxæmia within 2 weeks.

Group II. With less severe exposure symptoms do not appear until about the third week, when loss of hair, aplastic anaemia, pneumonia and severe gastro-enteritis result in death in the majority within 6 weeks.

Group III. In those who survive beyond the sixth week aplastic anaemia may become chronic, although many will still die from pneumonia, enteritis and other forms of secondary infection. Complete recovery is possible within 6 months but weakness and fatigue are common during convalescence.

Group IV. In mild cases leucopenia, diarrhoea and loss of hair may be the only abnormalities.

Protective Measures.—In atomic energy establishments, plutonium factories and research laboratories sources of intense radiation such as reactors and cyclotrons are surrounded with screens of thick concrete. Inhalation of radioactive gases is prevented by the use of gas masks or more elaborate air conditioning devices, and protective clothing is worn to prevent direct contact. When materials are exceedingly active they are encased in screened cells and are manipulated by remote control, often with the aid of periscopes or by television. Pollution of the atmosphere with radioactive dusts is prevented by means of filters fitted to the stacks, and contaminated waste water is rendered inactive in special delaying and treatment tanks before it is released into the rivers and seas. Many forms of monitoring devices are used to ensure the effectiveness of precautions. All workers carry film badges, fountain pen monitors or other forms of electrometers; they also undergo medical examination with blood counts at regular intervals. The radiation levels of the environment are estimated with continuously running dust monitors, Geiger counters and other instruments which are either portable or fixed.

DONALD HUNTER.

SECTION V

DISEASES OF METABOLISM

BASAL METABOLIC RATE

By basal metabolism is meant the metabolism of an individual when he is lying down completely relaxed and in the post absorptive state, *i.e.* about 12 hours after the last meal

Food, particularly protein will increase the metabolic rate, this increased metabolism being almost entirely due to increased activity of the liver. The metabolic rate of an individual is usually estimated by causing him to breathe into, and from, a closed system containing oxygen and also soda lime to absorb the exhaled carbon dioxide. The rate of oxygen consumption is recorded, and the heat produced when this amount enters into the combustion of foodstuffs is calculated. This is then, conventionally, divided by the surface area of the individual, expressed in square metres and calculated from the height and weight. This figure is finally expressed as plus or minus "x" per cent as compared with a normal average value.

Recent work has shown that there are several fallacies in expressing metabolic rate as a function of the surface area. In the first place, even in the normal metabolic rate is not strictly related to surface area, and secondly, variations in the ratio between surface area and the weight of metabolically active tissue frequently occur in abnormal states. This is well illustrated by subjects who are severely undernourished for their basal metabolic rate expressed conventionally in terms of surface area is very low, whereas when expressed in terms of metabolically active tissue it is only slightly below normal. In such subjects, the discrepancy seems mainly to be caused by a greatly increased extracellular fluid volume (shown, when extreme as famine oedema) which increases the calculated surface area without contributing anything to the metabolic rate.

Determination of metabolically active tissue is, however, difficult and is in itself somewhat arbitrary. It is very unlikely to be used in routine clinical practice with the existing methods of estimation.

DISTURBANCES OF WATER AND ELECTROLYTES

Normally water constitutes 60 to 70 per cent by weight of the body. Approximately 20 per cent of the body weight is due to extracellular water and 40 to 50 per cent to intracellular water. About one quarter of the extracellular fluid is composed of plasma and the rest constitutes the interstitial fluid. The main electrolytes in the extracellular fluid are the basic ions sodium, potassium and calcium and the acidic ions, chloride and bicarbonate. In the intracellular fluid, potassium and magnesium are the main anions and phosphate, bicarbonate, sulphate and protein are the main cations. When considering these substances it is more convenient to express them in milliequivalents (meq) than in mg, since 1 milliequivalent of a basic ion is equivalent to 1 milliequivalent of an acidic ion and thus in any solution the total concentrations of basic and of acidic ions are equal when expressed in this way. One milliequivalent of an ion is the ionic weight expressed in mg divided by the valency. Thus 23 mg of sodium is 1 milliequivalent and this would combine with 35.5 mg—or 1 milliequivalent of chloride and so on. The following are the

normal mean concentrations of the main electrolytes of plasma and of intracellular fluid :

Plasma				Intracellular Fluid			
Cations	meq/l	Anions	meq/l	Cations	meq/l	Anions	meq/l
Sodium	.. 140	Chloride	.. 100	Potass.	.. 153	Bicarb.	.. 11
Remaining		Bicarb.	.. 28	Magnes.	.. 43	Organic Phos-	
Cations	.. 10	Protein	.. 18			phate	.. 100
		Remaining				Protein	.. 67
		Anions	.. 4			Sulphate	.. 18
Total	.. 150		150		196		196

DEHYDRATION

Dehydration is the body state which results from an abnormally low water content. This lack of water may affect both intracellular and extracellular compartments, or the major deficiency may occur in only one of them.

In the last resort, too little body water must occur as a result of a negative body water balance, hence it arises from any condition resulting in the loss of water being greater than the intake. The intake of water is controlled largely by the sensation of thirst, the precise stimulus for which is not fully known. Water loss can be considered under two categories, namely, insensible loss and loss composed of urine, faecal water and the water content of any other bodily losses such as vomitus, intestinal contents from fistulae, etc. Insensible loss is normally of the order of 1,000 ml. per day, but the precise amount can only be measured with the greatest difficulty. The loss from the other sources can be precisely measured.

Urinary water loss is controlled to a very great extent by variations in the secretion of anti-diuretic hormone (A.D.H.) by the posterior pituitary. These variations occur as a result of impulses from cells in the hypothalamus called osmo-receptors which are sensitive to changes in the osmotic pressure of extracellular fluid. When this rises above normal there is an increased secretion of A.D.H. with the result that only small quantities of highly concentrated urine are produced—so lowering extracellular osmotic pressure. With too dilute an extracellular fluid the opposite occurs and large quantities of dilute urine are secreted.

The concentration of sodium ion in extracellular fluid is the major factor in controlling its osmotic pressure. Over 90 per cent. of the osmotic effect of the basic ions is due to sodium and the total quantity of acidic ions follows that of the basic ions, bicarbonate being controlled rapidly by means of metabolic processes and respiration. It can be seen, therefore, that, if for any reason the body becomes deficient in sodium, extracellular water is regulated so that the osmotic pressure of extracellular fluid remain as normal as possible. Hence a deficiency of sodium leads to an extracellular water deficiency, one form of dehydration. By contrast, excessive quantities of sodium in the body lead to retention of water and to oedema production, if the quantities involved are great enough.

If the body loses water directly and not as a result of sodium loss, this results in a shift of water from the intracellular to the extracellular water compartment. Loss of water only is thus reflected in a general increase in osmotic pressure in both compartments.

The mode of origin, symptoms and signs and the treatment of these two forms of dehydration are different so that the differential diagnosis is important.

"SODIUM" DEHYDRATION.—This occurs whenever the loss of sodium from the body is greater than the intake, e.g. vomiting, diarrhoea, profuse sweating. Thirst is not a feature of this form of dehydration. More characteristically patients suffer from languor, apathy, muscular cramps, weakness and fatigue. Headache may be

present and also a tendency to syncope on standing. Nausea and vomiting also occur and thus accentuates the dehydration. The skin is wrinkled and lacking in the normal elasticity. Reasonable quantities of urine are passed until the dehydration becomes extreme. With severe degrees of salt dehydration the patient enters a phase of oligæmic shock, with cold, clammy skin and peripheral cyanosis. Stupor and even sudden death may then ensue. The hæmoglobin and hæmatocrit are markedly raised owing to the hæmoconcentration and the plasma sodium tends to be low, though not markedly so until the condition has become very severe. Gastro intestinal function seems to be impaired as a result of salt depletion, and such considerable periods elapse before adequate amounts of salt have been absorbed from the alimentary tract that it is often advisable to correct the condition by giving salt solutions intravenously.

WATER DEHYDRATION—Water dehydration in which there is lack of water without corresponding lack of sodium occurs when a patient is too weak or ill and so cannot ask for drinks, and also in special conditions such as on rafts after shipwreck.

Intense thirst is a prominent feature of this form of dehydration, but the loss of intracellular fluid is greater than that of extracellular fluid, and, until the dehydration is severe, there is only a relatively slight increase in the hæmatocrit and hæmoglobin values. There is, however, a great diminution in urinary output and the urine which is produced is highly concentrated. The mouth becomes dry and thirst intense. When the water deficiency is becoming severe the face becomes pinched and grey and there is a diminution in muscular power. There may also be emotional lability and, when the dehydration is very severe, confusion and hallucinations.

Water taken by mouth is rapidly absorbed and produces improvement in the general condition in a matter of a few minutes.

OVERHYDRATION—By contrast with dehydration, overhydration occurs where the body water content is too high. By the mechanisms discussed above, it can occur either primarily as a result of too much water alone or secondarily to an abnormally great body sodium content, which itself results from a greater sodium intake than elimination (mostly by the kidney). As with dehydration, the two forms of overhydration produce quite different clinical pictures.

PRIMARY OVERHYDRATION—WATER INTOXICATION—This occurs as the result of an excessive quantity of body water, relative to sodium. It usually arises only in the presence of deficient renal function whether this be due to renal disease or occasionally in some general metabolic disturbance such as Addison's disease. It has been noted to follow the administration of large watery enemata to children with megacolon and to follow over-enthusiastic efforts to produce sodium depletion in patients with cardiac failure. Restlessness, muscle twitchings and later convulsions and coma are the main clinical features. It seems probable that these effects are mainly due to excessive intracellular water, since treatment by the injection of hypertonic saline (50 to 100 ml. of 5 per cent solution) causes a rapid improvement.

OVERHYDRATION SECONDARY TO SODIUM RETENTION—This form of water retention is that which, if it is great enough, gives rise to œdema, the excess being contained in the interstitial spaces. It is most commonly found in congestive heart failure, in certain renal diseases associated with massive proteinuria and in liver disease. In these conditions the kidney conserves sodium and, associated with this, a corresponding amount of water. Because œdema is secondary to sodium retention it is treated by measures which deplete the body of sodium, such as sodium restriction to a daily intake of less than 20 mEq (0.5 g.) large quantities (about 15 g. with each meal) of resins which absorb sodium from the alimentary canal and, where indicated, organic mercurial compounds. The latter act by preventing the renal tubules from reabsorbing sodium and, because of the osmotic effect of sodium in the tubular lumina, less water is reabsorbed so that a so called saline diuresis occurs.

ACIDÆMIA AND ALKALÆMIA

The normal reaction of the plasma is $\text{pH } 7.4 \pm 0.05$. When the hydrogen ion concentration is greater than this (the pH lower) a state of acidæmia exists, conversely, alkalkæmia occurs when the pH is higher than the above levels.

Owing to the efficient buffering action of the blood and body fluids, considerable alterations in the electrolyte levels can occur with comparatively small changes in pH , though it should be noted that a change of 1 pH represents a tenfold change in hydrogen ion concentration. Since, however, bicarbonate is the most labile ion (owing to its rapid turnover and to the rapidity with which it may be retained or excreted as CO_2 by the lungs), and since its concentration depends upon the difference between the other acid and the basic radicles, its plasma level is usually estimated in determining what degree of acidæmia or alkalkæmia is present. The fundamental consideration is that carbonic acid reversibly dissociates into hydrogen ions and bicarbonate ions thus

In accordance with the Law of Mass Action

$$k[\text{H HCO}_3] = [\text{H}^+] \times [\text{HCO}_3]$$

where $[]$ denotes "concentration of" and k is a constant. From this it follows that

$$\frac{1}{[\text{H}^+]} = \frac{1}{k} \times \frac{[\text{HCO}_3]}{[\text{H HCO}_3]}$$

$$\text{Since } \text{Log } \frac{1}{[\text{H}^+]} = \text{pH}$$

$$\text{pH} = \text{Log } \frac{1}{k} + \text{Log } \frac{[\text{HCO}_3]}{[\text{H HCO}_3]}$$

$$\text{Log } \frac{1}{k} = 6.1 \text{ for these circumstances}$$

$$\text{pH} = 6.1 + \text{Log } \frac{[\text{HCO}_3]}{[\text{H HCO}_3]}$$

It can thus be seen that the pH is linearly related to the logarithm of the ratio of bicarbonate to carbonic acid, it is not dependent upon the concentration of bicarbonate alone or of carbon dioxide alone. Normally the ratio of $[\text{HCO}_3]$ to $[\text{H HCO}_3]$ is 20/1. Thus normal $\text{pH} = 6.1 + \text{Log } 20 = 6.1 + 1.3 = 7.4$.

A disturbance of the acid base balance can arise either from metabolic causes such as failure of correct renal acid base regulation, or the production of large quantities of organic acid radicles as in diabetic ketosis, or from lack of proper respiratory function as in hysterical over breathing or in severe emphysema. In an acidæmia of metabolic origin, either a larger quantity of basic ions (largely Na^+) than acidic ions have been excreted by the kidney, or, by processes of metabolism or deficient renal function, an abnormal concentration of acid radicles has accumulated. In either case there is a smaller difference between the total ionic concentration of base and of non bicarbonate acid than usual. Thus the bicarbonate concentration will be lower than normal, usually, under these circumstances respiratory ventilation increases so lowering the plasma carbonic acid concentration and tending to restore the pH to normal. In addition owing to the loss of base there will be a loss of water and dehydration. By contrast if an acidæmia is of respiratory origin *e.g.* emphysema it arises because carbon dioxide cannot be expired at a normal tension and hence the concentration of carbonic acid in the plasma becomes abnormally high. Owing to the relationship between this pH , and bicarbonate concentration shown earlier, the level of bicarbonate must also rise if the pH is to be kept within the range compatible

with life. The total electrolyte balance under these circumstances is maintained largely by the excretion of chloride by the kidney. Hence in respiratory acidæmia, the concentration of plasma bicarbonate is higher than normal.

It can be seen from the foregoing that, in order to obtain a reasonably correct interpretation of acid-base balance, it is really necessary to estimate two of the three related factors pH , (HCO_3^-) , and (H_2HCO_3) . However, if it is known whether the primary fault is metabolic or renal on the one hand or respiratory on the other, an estimation of (HCO_3^-) alone should reveal any tendency towards acidæmia or alkaliæmia.

ALKALI RESERVE.—In the above discussion this term has been carefully avoided, since it has no really precise meaning and it may actually be misleading. Originally applied to the plasma bicarbonate concentration, and implying that the amount of alkali (largely sodium ion) corresponding to this was available in reserve to deal with any increase in acid radicals which might occur, the term is now sometimes referred to the plasma CO_2 content. Actually the alkali corresponding to the bicarbonate cannot all be considered as a physiological reserve, since death occurs before the bicarbonate is all replaced; furthermore, as previously shown, in respiratory acidæmia the total amount of bicarbonate is greater than normal.

ACIDÆMIA

The main conditions encountered in practice which give rise to acidæmia are chronic renal deficiency, where the kidney cannot excrete the excess of acid over basic radicals which are present in a normal diet, acute diarrhœa where a large amount of base is lost in the stools, diabetic acidosis where, in association with defective carbohydrate metabolism, a grossly excessive quantity of organic acids is produced, and acute starvation where carbohydrate is not metabolised in normal amounts and there is a secondary production of organic acids. Prolonged vomiting may or may not produce acidæmia depending on whether the acid lost in the vomitus either is not or is great enough to be balanced by the organic acid production which results from the lack of food intake. As explained above, acidæmia also accompanies insufficient respiratory function from whatever the cause and it also occurs after profuse hæmorrhage.

The main symptom of acidæmia is an increase in the depth and rate of respiration, though this only becomes apparent when the degree of acidæmia is quite severe. The breathing is deep and relatively quiet, though owing to the rapid air flow there may be a hissing sound. This type of breathing is known as acidotic breathing or Kussmaul's respiration. Signs of sodium dehydration are usually also present.

In severe degrees of acidæmia the pH of the blood may exceptionally fall to 7.0 and, if the cause is renal or metabolic, the bicarbonate may fall as low as about 5 meq. per litre (11.0 volumes of CO_2 per cent.).

ALKALIÆMIA

Most commonly this condition occurs as a result of the ingestion of excessive quantities of alkali often because of peptic ulcer. It also occurs in patients with pyloric stenosis who vomit large quantities of acid fluid. It is sometimes found associated with renal failure, but here there has usually been an excessive intake of alkali, given to combat the acidosis which is commonly present initially. Hyperventilation by hysterical individuals can also give rise to quite serious degrees of alkaliæmia. A mild alkaliæmia is often found in Cushing's syndrome.

Symptoms.—There may be no symptoms even in the presence of a severe alkaliæmia. However, loss of appetite, nausea and vomiting may occur and may be accompanied by headache and mental abnormalities. Many of these symptoms,

however, might arise from other abnormalities accompanying the alkalemia and slow, shallow respirations and tetany are the only clinical symptoms which can be definitely ascribed to all alkalemia. The kidneys may become damaged, the urine containing blood, protein and casts. If the alkalemia is severe enough and is not treated, death in coma may occur.

The pH of the blood may be raised up to a limit of about pH 7.6 and, where a metabolic or renal abnormality underlies the condition, the plasma bicarbonate may be raised up to a limit of about 55 meq/l (120 volumes of CO_2 per cent).

POTASSIUM

Body potassium is largely situated inside cells. The total body content of potassium is about 4000 meq (100 g) in an adult man, and of this only about 80 meq (2 g) is extracellular. The normal concentration of potassium inside cells is about 150 meq/l whereas the normal extracellular concentration is 4 to 5 meq/l (15 to 20 mg/100 ml). It is to be emphasised that a low intracellular potassium content is not necessarily accompanied by a low extracellular (and therefore plasma) potassium concentration. Indeed, as in some cases of untreated diabetic coma, the plasma potassium may be abnormally high in association with an intracellular potassium depletion, if, however, a low plasma potassium concentration is found, there is almost certain to be an intracellular potassium deficiency. Since it is not practicable to estimate intracellular potassium in clinical practice, as with all other clinical problems involving water and electrolytes, a general clinical appraisal of the situation is just as important as a determination of the plasma concentration in deciding on the likelihood of potassium depletion or excess.

In equilibrium the bodily intake of potassium is equal to its loss. This, with a normal diet is of the order of 65 meq (2.5 g) per day. The kidney, however, is not generally able to secrete a urine containing a lower potassium concentration than the plasma, so with a urinary volume of say 1000 ml per day at least 4 to 5 meq (160 to 200 mg) of potassium must be lost each day in the urine even if there is no intake. Urinary losses, however, may be much higher than the normal intake in such conditions as nephrocalcinosis (base-losing nephritis), diabetic acidosis, the post operative state, adreno cortical overactivity (e.g. Cushing's syndrome) and overdosage with desoxycorticosterone.

A more frequent cause of potassium deficiency is excessive loss from the alimentary tract and this may or may not be associated with deficient intake. Thus pyloric stenosis, gastro enteritis, ulcerative colitis, fatty diarrhoea and continuous aspiration of intestinal contents as carried out after operations on the alimentary tract and in paralytic ileus, may all lead to potassium depletion.

Excess body potassium occurs in Addison's disease and in renal deficiency, otherwise it is almost always the result of therapy when more potassium has been given than can be excreted. In the presence of poor renal function it is as dangerous to give potassium salts by mouth as by any other route.

It can be seen that in theory four possible potassium abnormalities might occur, namely, increased intracellular potassium, increased extracellular potassium, decreased intracellular potassium and decreased extracellular potassium. Owing to the difficulties involved in estimating intracellular potassium the clinical syndromes associated with intracellular abnormalities are by no means so clearly defined as those occurring with abnormal extracellular potassium concentrations.

A low concentration of extracellular potassium is associated with changes in the electrocardiogram, most notably prolongation of the Q-T interval, a decrease in the voltage and a prolongation of the T wave and a depression of the S-T segment. Paralysis of voluntary muscle and death from cardiac arrest may also occur. The levels at which these phenomena occur are by no means constant and depend to some

extent upon other ionic concentrations, they are, for example, more marked at a given potassium level in the presence of a high sodium or calcium level and in the presence of an acidosis. No serious manifestations should occur with concentrations above about 2.5 meq/l (10 mg per 100 ml) and they are usually preceded by electrocardiographic changes which, although not specific for hypokalaemia, serve as a good clinical index of the situation. Death occurs at a concentration of about 1.5 meq/l (6 mg per 100 ml).

A high extracellular potassium may also be associated with voluntary muscle paralysis and in both cases the deep reflexes may be preserved in the early stages. It is not easy on clinical examination to distinguish between the two forms of paralysis, but a consideration of the clinical history and an examination of the electrocardiogram will give quite unequivocal differentiation, since high levels of extracellular potassium give electrocardiographic changes consisting of an increase in the voltage of the T waves followed at higher levels by a prolongation of the P-R interval, finally the ventricular complex assumes a saw-tooth appearance. Again, the levels at which the changes occur are not constant and depend on other ionic concentrations, but no serious complications should take place unless the serum potassium concentration is over 7.5 or 8 meq/l (30 to 32 mg per 100 ml). Death from cardiac arrest is liable to occur in the region of 10 meq/l (40 mg per 100 ml) and it may not be preceded by muscle paralysis. Marked bradycardia resulting from heart block may occur and give clinical warning of the situation.

The syndrome associated with a low intracellular potassium content is not clear-cut, though many effects have been ascribed to it. Apathy and lethargy, confusion and disorientation, intestinal ileus and peripheral oedema, have all been suggested as resulting from this state, and necrosis of heart muscle has also been shown to occur. It has been shown experimentally that depletion of the order of about 300 meq (12 g) is not associated with any of these symptoms. It should be remembered, however, that an intracellular depletion of 300 meq (12 g) is one of only about 10 or 12 per cent, whereas it is more than four times the total amount normally present in the whole of the extracellular fluid. Thus, patients with intracellular potassium depletion are in a potentially dangerous situation, since anything which causes a rapid transfer of potassium into cells might result in severe extracellular potassium deficiency. Such a situation occurs when diabetic coma is treated, since the stimulation of carbohydrate metabolism results in a transfer of potassium from the extracellular to the intracellular compartment, and this may be accompanied by muscle paralysis and death.

Treatment of potassium deficiency—Potassium salts must only be given with proper precautions because of the dangerous effects of high extracellular potassium levels. In the presence of a normal renal function it is relatively safe to give potassium by mouth in doses up to 150 meq (about 10 g of KCl) spread over 24 hours. Such a dose, however, could be rapidly lethal if given to a patient with a poor renal function. Intravenous infusions given to replace lost intracellular potassium must, for practical reasons, contain a much higher potassium concentration than plasma (e.g. 40 meq/l = 0.156 g per 100 ml). Thus they must only be given very slowly and frequent plasma potassium estimations should be made or frequent electrocardiograms taken.

Except in occasional and unusual cases more than 1 litre of the above solution in 3 hours should never be given.

Treatment of potassium intoxication—If the level of extracellular potassium is so high as to necessitate emergency treatment it can be temporarily lowered by the intravenous injection of 25 to 50 units of insulin, together with 50 or more grammes of glucose by mouth. This will cause a temporary transfer of potassium into cells.

The effects of high extracellular potassium levels can also sometimes be diminished by giving calcium (e.g. 2 to 4 g of calcium gluconate intravenously) or sodium when this ion is deficient, but these measures are not so effective as glucose and insulin.

If the high potassium results from adrenal deficiency then deoxycortone acetate (D O C A) 10 mg intramuscularly should also be given at once, and the underlying condition subsequently treated in the usual way (see Addison's Disease). If, however, as is usual, the hyperpotassaemia is due to deficient renal function, potassium must be removed by means of peritoneal dialysis, by the use of an artificial kidney, or by taking 50 to 100 g per day by mouth of a kationium resin charged with ammonium or sodium.

GEORGE A. SMART

DIABETES MELLITUS

Definition—Diabetes mellitus is not a disease entity, but includes a variety of related disorders of metabolism, having in common an increase in blood sugar, usually accompanied by glycosuria. In most of these there is also a greater or lesser tendency to ketosis, which is the most important immediate danger, and an increased liability to various forms of vascular degeneration, which are the most serious long term risks.

Prevalence—It is estimated that there are between 150,000 and 200,000 known diabetics in Great Britain and the incidence as everywhere is rising. Further, 'detection drives' in the U.S.A. and elsewhere have shown fairly constantly that there are nearly as many mild undiagnosed cases as there are known ones, and the same may well be true in this country. Since the majority of diabetics are over the age of 40, and since the proportion of the population over the age of 40 is rising rapidly, it is likely that in 20 years' time 500,000 or nearly 1 per cent of the population will be diabetic.

Though insulin has revolutionised the outlook for the diabetic in certain respects—the expectation of life of a 10 year old diabetic child is now 45 years instead of 13 years in the pre-insulin era—it has not prevented an alarming incidence of complications, particularly retinopathy, nephropathy and arteriopathy in those who have had the disease for some years. How far these complications are due to factors which cannot be controlled by insulin and diet and how far to avoidable poor control of the diabetic state is not yet known, but the question must be regarded as one of the major problems of modern medicine.

Ætiology—Knowledge of the ætiology of diabetes is quite incomplete, but two factors of importance have been recognised, an inherited tendency and overnutrition. There are two kinds of evidence for an hereditary tendency. First a history of diabetes in one or more blood relatives is much commoner in diabetics than in non diabetics, and secondly, concordance (i.e. both twins developing diabetes) is five times as common in identical twins as in fraternal twins. Identical twins indeed often develop diabetes of about the same severity, within a short time of each other. How far diabetes mellitus is genetically homogeneous and how the tendency is inherited is uncertain. It has been suggested that it is homogeneous—that the tendency is inherited in a simple recessive manner and that if all potential diabetics lived to the age of 90, the numbers actually developing the disease would be in accordance with this hypothesis. On the other hand it has been suggested that the disease is heterogeneous, the severe early-onset cases being determined by recessive genes and the mild late-onset cases by dominant genes. If the assumption of recessive inheritance is correct for all diabetics, it appears that the number of carriers of the gene in the population is in the order of 25 per cent. Further, if it is proved that a considerable proportion of cases of diabetes are hereditary, this affection must rank as the most important, numerically and socially, of all hereditary diseases.

The importance of overnutrition is shown by the fact that over the age of 40 some 80 per cent. of patients developing diabetes are, or have been, considerably overweight. Broadly speaking both the incidence and mortality of diabetes after middle

age vary directly with the degree of obesity; and in the War of 1914-1918 and the War of 1939-1945 both incidence and mortality fell with rationing.

It appears likely that when the inherited tendency is strong enough, the subject develops diabetes in childhood or youth without becoming fat; though the onset often follows a period of active growth, and children tend to be above average height when they develop the disease. If the inherited tendency is less strong, the disease becomes manifest only when precipitating factors "bring out" the inherited predisposition. The most important of these is obesity, though infection may act temporarily in the same way, and so possibly may nervous shock.

The disease is apparently commoner in urban than in rural communities, and in Jews than in Gentiles. These differences may well be due to habits as regards diet and physical exercise. It is possible that trauma, like any other form of shock, might hasten the time at which a person with latent diabetes manifests symptoms. The absence of an increased incidence of the disease in the battle casualties of the War of 1914-1918 and the War of 1939-1945 indicates that trauma can play no more important part than this, except in excessively rare cases in which a large part of the pancreas is destroyed.

Pathology.—In 1889 Minkowski produced diabetes experimentally by removing the pancreas from a dog. Langerhans had described his islets in 1869, and the hypothetical internal secretion of the pancreas was named "insuline" long before it was isolated. How it was finally isolated in 1921 after only a few months' work by Banting, then a young orthopaedic surgeon, and Best, a junior graduate assistant, is one of the medical romances of the century.

The pathogenesis at that time appeared deceptively simple. (Lack of insulin due to a defect of the islets reduced the ability of the tissues to utilise glucose, which therefore accumulated in the blood, and was excreted in the urine. Impaired oxidation of glucose led to a hold-up in the metabolism of fat, so that intermediary products accumulated in the blood and led to ketosis.) It soon became apparent, however, that this was an oversimplification. Histological studies on the pancreas showed that whereas in some human cases various changes, including fibrosis, hyaline changes and hydropic degeneration of the β cells are found in the islets, in at least 25 per cent. these are quite normal. Further, a number of patients have now survived total pancreatectomy and presumably have no insulin secretion of their own. They have been found to develop a moderate degree of diabetes easily controlled by 40, or at most 60, units of insulin a day. Since many "idiopathic" diabetics require well over 100 units a day, their diabetes cannot be due to a simple lack of insulin secretion.

A great deal of experimental evidence has implicated other endocrine glands, particularly the anterior pituitary. Indeed, the condition has been produced in suitable animals by injections of crude anterior pituitary extracts, and more recently of purified growth hormone. This fits in with the clinical observation that mild diabetes is seen in some cases of hyperpituitarism. It also might explain why diabetic women not only tend to have large babies, but sometimes give a history of having given birth to large babies long before they developed diabetes. It has been suggested that the growth hormone leads to growth as long as adequate insulin is available (and may increase the secretion of insulin for this purpose) but to diabetes where the supply of insulin is inadequate.

The explanation of the hyperglycemia and glycosuria as due to the failure of the tissues to oxidise glucose has also been untenable for many years, at least in the simple form in which it is usually propounded. In 1923 Mann succeeded in removing dogs' livers. Such animals rapidly use up their available glucose and die in hypoglycemic convulsions. It was soon shown that this is also true of diabetic dogs, who in the absence of the liver, die in hypoglycemia as rapidly as non-diabetic ones; an observation which is incompatible with "under-utilisation" of glucose as the sole explanation of hyperglycemia. Indeed it appears from the experimental work

of Soskin, amongst others, that one factor in the hyperglycæmia is the "overproduction" of glucose by the liver. In the normal animal there is a kind of "thermostatic" mechanism whereby a fall in blood sugar leads to an increased output of glucose from the liver and vice versa. In diabetes the "thermostat" is set at a higher level than normal, for indeed the liver goes on putting out glucose in an uncontrolled fashion to the limit of its capacity. Recent studies with radioactive glucose show, however, that underutilisation in the tissues is also important.

Similarly the "oxidation" of glucose in the tissues is an oversimplification. Molecular oxygen does not react directly with foodstuffs. The oxidative breakdown of energy materials in the tissues occurs by a series of reactions, including oxidation, reduction, decarboxylation, addition of CO_2 , phosphorylation, hydrolysis and transamination. The most important step is the formation of glucose-6-phosphate from glucose and this reaction is catalysed by an enzyme hexokinase. It has been suggested that hexokinase is inactivated by anterior pituitary hormone in the absence of insulin, and that this is the point at which insulin exerts its main effect. Fortunately ability to use insulin therapeutically has not had to await the exact elucidation of its pharmacological actions, which is still far from complete.

It does seem, however, that our concept of diabetes is approaching a new synthesis. It may be said that we depend for survival among other things on a delicate homeostatic mechanism which keeps the blood sugar in normal persons in a narrow range from about 70 to 160 mg per cent. The most vital part of this mechanism is that which raises the blood sugar and prevents hypoglycæmia and unconsciousness in starvation, and this seems to be a function of the anterior lobe of the pituitary and the adrenal cortex. Insulin, which alone of the hormones lowers the blood sugar, is less immediately important.

Diabetes may be regarded as an imbalance in this mechanism, in which the blood sugar-raising factors predominate over blood sugar-reducing ones. Exhaustion of the islets of Langerhans with permanent changes in their structure may follow. Meanwhile the organism starves in the midst of plenty, and many features of its metabolism, including the tendency to ketosis, can be explained as analogous to those of starvation. It may well be, as Harold Wolff has recently suggested, that diabetes mellitus should be regarded as an inappropriate use of an adaptive-protective reaction, the anterior pituitary-adrenal mechanism which prevents hypoglycæmia in starvation.

Clinical Picture—The classical onset with severe thirst, polyuria and loss of weight is seen in a minority, perhaps one third of cases. Lack of energy, muscular weakness, mild thirst and some loss of weight are found in perhaps another third if enquiry is made about them. Definite increase in appetite is unusual, though it is a safe generalisation in this country that real loss of weight with an increased appetite means either thyrotoxicosis or diabetes mellitus. Pruritus vulvæ and varying degrees of vulvitis are common in women, but generalised pruritus due to diabetes must be excessively rare, if it ever occurs. Men occasionally notice that spots of urine on their trousers dry leaving a white deposit, and some complain of impotence.

A few patients are virtually symptomless, the glycosuria being discovered when the urine is examined as a routine for life insurance or other purposes. Almost one fifth present with symptoms of complications. Of these a very few patients are first seen in diabetic coma, or with severe neuropathy. Others are detected by ophthalmologists who see micro aneurysms or other evidence of diabetic retinopathy, in antenatal clinics and by gynaecologists among women referred for vulvitis. A few are discovered by testing the urine of patients with boils and other staphylococcal skin infections.

It may be said that a majority of diabetics fall into one of two groups. The older and fatter tend to have mild symptoms with an insidious onset, more often present with a complication, have little tendency to ketosis and are relatively insensitive to insulin. The younger and thinner more often have severe and classical

symptoms, with a definite onset, are very liable to ketosis and are sensitive to insulin.

Physical examination shows nothing in mild uncomplicated diabetes. In severe cases there may be weakness and wasting with some degree of dehydration. In more severe cases a dry brownish tongue, the odour of acetone in the breath and an enlarged tender liver may indicate that the patient is in impending coma. As many patients have complications by the time they consult a doctor, no initial examination of a diabetic is complete without examination of the eyes for lenticular opacities and retinopathy; of the chest for signs of tuberculosis (and a radiograph of the chest should be taken, even if no signs are found); of the skin for septic infections; of the legs for loss of knee and ankle jerks and other signs of diabetic neuropathy, and of the feet for loss of pulsation in the dorsales pedes and posterior tibial arteries or other signs of impaired blood supply.

Diagnosis. Urine testing.—The importance of routine urine testing for sugar will be evident from what has already been said. Benedict's test is preferable to Fehling's, but must be correctly performed. "Clinitest" and "Glucotest" are satisfactory and trouble-saving substitutes, provided the makers' instructions are followed exactly. A positive result with any of these tests indicates that a reducing substance is present in the urine, but not that the substance is glucose. "False positives" may be due to drugs such as aspirin, salicylates, chloral hydrate and ascorbic acid, or to the presence of other sugars, of which lactose in pregnant and lactating women is the only one of clinical importance.

In practice slight colour changes (*i.e.* a green colour) with Benedict's test should be ignored, or left for elucidation by a biochemist. A definite reduction (*i.e.* a yellow or red deposit) in an untreated patient with definite thirst and polyuria, is for practical purposes diagnostic of diabetes, and further investigations are unnecessary. If a definite reduction is found in a patient with no symptoms or with doubtful symptoms, it is best to proceed to the determination of a single blood sugar taken 1 to 1½ hours after a meal containing at least 80 g. of carbohydrate or to a sugar tolerance test.

The urine should also be tested in every case of suspected diabetes by Rothera's sodium nitroprusside test and Gerhardt's ferric chloride test for the presence of ketone bodies. The clinical significance of these two tests is often not understood. The nitroprusside test is specific for ketone bodies, but is extremely sensitive so that it may be positive in the presence of a clinically very mild ketosis. A red or purple colour with the ferric chloride test may be produced by ketone bodies or by drugs, notably aspirin and salicylates and sodium aminosalicilate. In the former case the test will be negative if performed on boiled urine, since ketone bodies are volatile. The ferric chloride test, however, is relatively insensitive, and therefore if both tests are positive a ketosis of some severity is present. The practical significance of different findings with these tests is summarised in the table on p. 426.

(6) Blood sugars and the glucose tolerance test.—In each case the patient should have been eating a normal amount of carbohydrate for at least a week before the test, since a normal person after a few days on a reduced carbohydrate diet may show an abnormal blood sugar curve. For this reason patients found to have glycosuria, without definite diabetic symptoms and without ketosis, should never be put on a diet until the diagnosis has been confirmed by further investigations.

A clinically probable diagnosis of diabetes mellitus can be confirmed by estimating a single blood sugar 1 to 1½ hours after a meal containing at least 80 g. of carbohydrate. If this is over 180 mg. per cent., the diagnosis is confirmed.

In symptomless glycosuria and in any case in which the diagnosis is really in doubt, it is wise to perform a glucose tolerance test. A normal blood sugar curve (*i.e.* a fasting blood sugar of under 110 mg. per 100 ml., rising to less than 180 mg. per 100 ml. in half an hour and returning to the fasting level within 2 to 2½ hours) with sugar in one or more corresponding specimens of urine indicates a lowered

renal threshold or renal glycosuria. This is a harmless anomaly and requires no treatment. The so called "lag storage" or "steep" curve in which the blood sugar at half an hour rises to above 180 mg per 100 ml but returns to the fasting level within the usual time is also usually regarded as a harmless anomaly. In frank diabetes the fasting blood sugar is above 110 mg per 100 ml rises above 180 mg per 100 ml and either continues to rise or fails to return to the fasting level in 2 to 2½ hours. Provided the carbohydrate intake over the previous week has been adequate, and provided other causes of abnormal sugar tolerance, *e.g.* sepsis, thyrotoxicosis

Sugar	Nitroprusside test	Ferric chloride test	Significance
+++ <i>i.e.</i> 2 per cent or more	—	—	Probably D M but no immediate danger or urgency
+++	+	—	D M with mild ketosis
+++	++	++	D M with severe ketosis requiring urgent investigation and treatment
+++	—	+	Probably a diabetic who has taken aspirin or salicylates
—	+	—	Mild ketosis due to other causes, <i>e.g.</i> vomiting in children or starvation

severe liver disease, hyperpituitarism and hypercortico adrenalism can be excluded a curve in which the blood sugar rises above 180 mg per 100 ml at half an hour and does not return to the fasting level at 2 to 2½ hours should be regarded as indicating diabetes mellitus. It may be added that the chief value of the glucose tolerance test is in excluding diabetes mellitus, and there is never any indication to perform it on a known diabetic under treatment with insulin.

Treatment—The decision whether to treat a patient by diet alone or with insulin depends on the severity of the symptoms, the presence or absence of complications and the patient's age and weight and not on the results of special investigations such as the glucose tolerance test. Obese adult patients with mild diabetes and no ketosis nearly always can and should be treated with a diet which will reduce their weight. Underweight patients with severe symptoms and especially with ketosis should always be treated with insulin, and so should children. In the case of adult

patients whose weight is in the normal range and who have no ketosis and no complications, it is justifiable to try the effects of a moderate reduction of the carbohydrate in the diet, but this form of treatment should not be continued for long unless control is good with progressive loss of weight

Treatment will therefore be described under the following headings

(a) Treatment of obese patients by diet alone

(b) Use of insulin

(c) Treatment of patients with severe ketosis

(a) Treatment of obese patients by diet alone—Such patients are usually over middle age and have mild diabetic symptoms or no symptoms. They quite frequently, however, have some complication, such as retinopathy, by the time they come for treatment. The treatment is that of obesity (*qv*). If such patients adhere to a diet of C 1,200 to C 1,400, diabetic symptoms, such as thirst and polyuria, disappear, and the hyperglycæmia and glycosuria are usually rapidly controlled. If the weight is substantially reduced or reduced to normal, such patients are often able to eat a more liberal diet without a return of the diabetic state. But if the weight is allowed to increase again, the diabetic state returns. Amphetamine or dextroamphetamine 5 to 10 mg in the morning and at midday may be prescribed to assist those who genuinely try to diet, but whose appetite defeats them. It is useless in the case of those who will not even try to diet.

Difficulty arises with overweight patients who fail to lose weight, especially if they have complications such as retinopathy or obliterative arterial disease. Insulin should be avoided if possible, since such patients are usually insulin resistant and if treated with large doses of insulin, their weight only increases further.

(b) Use of insulin—Underweight patients must be treated with insulin since a diet of low calorie value would only lead to further loss of weight. It is important that the objectives of treatment with insulin should be understood. These are

- (1) To enable the patient to live as normal a life as possible, earn a living and take part in ordinary activities. To achieve this it is necessary for him to learn more about the management of his own illness than is considered wise in any other condition. The main part of the work of a physician treating diabetics is to teach them how to look after themselves.
- (2) To keep the patient free from any symptoms of diabetes and from anything more than minor and occasional symptoms of hypoglycæmia throughout the 24 hours, and free from ketosis at any time.
- (3) To keep the urine as free from sugar as possible and the blood sugar as near normal as possible, provided the attainment of this does not interfere with (1) and (2). It is, for instance, misguided to achieve a sugar free urine for most of the day, if this means that the patient has hypoglycæmic attacks so frequently that he is unable to earn his living or that he has to spend most of his spare time testing his own urine and weighing out his food. There is, however, considerable room for skill in attaining (3) within the limits set by (1) and (2).

Insulin is a protein of molecular weight of 35 200. It is destroyed by the gastric secretion, and therefore cannot be given by mouth. It is usually injected subcutaneously, though it can also be given intramuscularly and intravenously.

It is biologically standardised and the international standard preparation is a quantity of pure dried crystalline insulin hydrochloride, 1 mg of which contains 22 units of activity. It is supplied in strengths of 20 units per ml (single strength), 40 units per ml (double strength) and 80 units per ml (quadruple strength). Since on most syringes 1 ml is divided into ten divisions, each division corresponds to 2, 4 or 8 units. Insulin should therefore, be prescribed in multiples of 4 or 8, and not of 5 and 10.

There are unfortunately seven different preparations available in different strengths in Great Britain at the present time. The important ones are

INJECTIO INSULINI (B.P.)—"Soluble", "Regular" or "clear" insulin. Available in strengths of 20, 40 and 80 units per ml. Acts quickly and strongly. Action starts within half an hour and lasts 6 to 8 hours with doses up to 40 units, but up to 12 hours with very large doses. Hypoglycæmic symptoms most commonly occur 2 to 4 hours after injection, but may be delayed up to 8 hours or more with very large doses.

Soluble insulin is used

- 1 In diabetic coma and severe ketosis (*q.v.*)
- 2 Three doses of soluble insulin a day, i.e. one dose before each main meal is often employed temporarily when specially strict control is necessary, e.g. at the beginning of treatment, during infections, before and after operations, in the latter months of pregnancy and in patients with active pulmonary tuberculosis.
- 3 Two doses of soluble insulin a day, i.e. before breakfast and before the evening meal, was for many years the standard treatment for all diabetics on insulin. It is still a useful method for those who are used to it and prefer not to change, for a few diabetics who are difficult to control on a single dose of any insulin and for those requiring very large doses. (More than 80 units of any insulin in one dose should be avoided if possible, on account of the danger of severe hypoglycæmia.) On this régime one-third of the carbohydrate should be taken at breakfast and one-third in the evening meal, with a small lunch and tea and a snack at mid-morning and last thing at night.

4 Withdraw needle from P Z I bottle and give injection immediately

The object of this routine is to avoid transferring P Z I to the bottle of soluble insulin

By varying the proportions of P Z I and soluble insulin, it is possible to control many diabetics on a single morning dose, the main disadvantage of the regime being the danger of hypoglycæmic reactions at night. It seems likely that in the future a single injection of Insulin Zinc Suspension (Danish "Lente") or of a mixture of Insulin Zinc Suspensions will replace mixtures of P Z I and soluble in most cases.

GLOBIN INSULIN WITH ZINC, prepared from ox globin, insulin and zinc, usually has an action midway between that of soluble and P Z I, that is to say, the action comes on in about 2 hours and lasts from 12 to 18. Hypoglycæmic reactions after a dose given before breakfast usually come on at midday or in the afternoon. The carbohydrate should, therefore, be distributed with rather more than one-third at lunch-time, one-fifth each at tea and supper, and one-fifth or rather less at breakfast, with small snacks at mid-morning and last thing at night. Globin insulin is useful for controlling some middle aged and elderly diabetics, who do not need more than 40 units a day. If attempts are made to control more severe diabetics with a single daily dose of this insulin, they are often found to be hypoglycæmic at midday or in the early afternoon and at the same time to have diabetic symptoms (thirst, etc) during the night.

INSULIN ZINC SUSPENSIONS (Danish "Semilente", "Lente" and "Ultralente").—It has recently been found that the phosphate previously used as a buffer inhibited the delaying action of zinc. The new Danish preparations consist of insulin precipitated with very small quantities of zinc and resuspended in an acetate buffer without the addition of any protein or protamine. The length of action was found to vary with the size and form of the insulin particles. Insulin Zinc Suspension Amorphous (Danish "Semilente", available in strength of 40 units per ml) has an action lasting up to about 16 hours. Insulin Zinc Suspension Crystalline (Danish "Ultralente", available in strength of 40 units per ml) has an action lasting up to 30 hours or more. A mixture of the two, consisting of 3 parts of amorphous to 7 of crystalline, Insulin Zinc Suspension (Danish "Lente", available in strengths of 40 and 80 units per ml) has an action of approximately 24 hours, and has been introduced as the preparation likely to control most diabetics when used in a single dose. Mixtures in any proportions desired can, however, be made up from the amorphous and crystalline preparations, and will remain stable at ordinary temperatures.

I Z S (Danish "Lente") is the variety which has been most used in this country at the time of writing. It appears that the effect is much like that of a mixture of P Z I and soluble, except that hypoglycæmic reactions appear to be less common. With a single morning dose, these may occur during the morning or afternoon but rarely, if ever, at night. Local reactions to the injection are much rarer than with the older insulins. The carbohydrate in the diet should be distributed in three main meals, a quarter each at breakfast, lunch and tea, with a snack during the morning and a small supper in the evening.

Insulin Zinc Suspension Crystalline (Danish "Ultralente") appears to have much the same length of action as P Z I or an even longer one. Insulin Zinc Suspension Crystalline (Danish "Semilente") is said to act for 12 to 16 hours, which would be somewhere between soluble insulin and globin zinc insulin. The action of I Z S "Lente" can be lengthened by adding I Z S crystalline "Ultralente" or shortened by adding I Z S amorphous "Semilente", or a mixture of any proportions of I Z S crystalline and I Z S amorphous can be made up to suit an individual patient. Insulin zinc suspensions cannot be mixed with P Z I or globin insulin.

Choice of insulin—There is no indication to change the regime of patients who are happy and doing well on two doses of soluble or on one dose of either P Z I or globin insulin. I Z S (Lente) should be tried on patients who are poorly controlled

on their present regime, on patients who dislike two injections a day, or on patients who are subject to frequent hypoglycæmia on their present regime and on patients who show allergic reactions to other types of insulin. When the transfer is made the distribution of carbohydrate in the diet must be altered to that already stated. The total dose of the previous regime should be given as I Z S (Lente) before breakfast. Regular urine tests should then be made. The dose of insulin or the distribution of the carbohydrate in the diet may have to be adjusted, and if significant glycosuria is still found at bedtime or on rising, I Z S Crystalline (Ultralente) may have to be added to the I Z S (Lente).

Control of insulin dosage—Good control means first a state in which the patient feels well, leads a normal life and is free from symptoms, and this is more important than normal biochemical findings. Further, the correct dose of insulin can only be determined when the patient is at home and leading a normal life. Patients with a normal renal threshold can usually be controlled satisfactorily by urine tests. Few, if any, such patients can maintain a sugar-free urine throughout the day without periods of hypoglycæmia, and a very few can never be got sugar free for any time without becoming hypoglycæmic. One should, however, aim to get the urine sugar free at some times during the day, even if temporary glycosuria occurs after the main meals. In determining how far this has been achieved, a record of a patient's own urine testing over a day or two of normal activities is of more value than is a single urine test or even a blood sugar under the abnormal circumstances of a visit to the doctor or the diabetic clinic. Reasonably intelligent and co-operative patients can all be taught to use the "Clinitest" apparatus.

If a patient, particularly an elderly one, is too easily controlled and shows constantly sugar-free urine without hypoglycæmia, one should suspect a high renal threshold. If a patient has frequent hypoglycæmic attacks, but is rarely or never sugar free, one should suspect a low renal threshold. In such cases the approximate level of the threshold can be determined by performing a series of simultaneous blood and urinary sugar estimations. Patients with low and high renal thresholds should have this information clearly marked on their records. The main indications for blood sugars in the control of treatment occur in dealing with such patients.

Some patients remain well controlled on a given dose of insulin for long periods. Others need more or less frequent adjustment of their doses. Sudden loss of control with heavy glycosuria or ketosis may be due to

- 1 Infections such as colds, influenza, urinary infections, boils, injection abscesses or pulmonary tuberculosis
- 2 Mistakes in measuring insulin, a leaking syringe or failure to take insulin
- 3 Worry or "aggravation"
- 4 Serious dietary indiscretions

Hypoglycæmia may be due to

- 1 Too large a prescribed dose or a mistake in measuring dose of insulin
- 2 Missing a meal
- 3 Unusual exertion

Hypoglycæmia—The usual symptoms are a sense of apprehension, hunger, sweating, trembling, palpitation and unsteadiness, which may progress to stupor, coma and convulsions. Some patients become emotionally unstable, or aggressive or behave as if they were drunk. With protamine zinc insulin headaches and lassitude may be complained of, particularly in the early morning, and nocturnal reactions may occur in which the patient may have night sweats or may pass into a convulsion without waking up. A few patients become unconscious almost without warning and old people may develop prolonged confusion. It is wise to think of hypoglycæmia whenever a patient receiving insulin complains of an unusual sensation or behaves in an unusual manner.

All diabetics on insulin should carry sugar (or glucose tablets) and take 2 to 4 lumps (10 to 20 g.) as soon as they recognise the symptoms. Many semi-comatose and uncooperative patients can be brought around if their heads are held firmly under the arm and spoonfuls of syrupy sugar solution are forced into their mouths. If the patient is comatose, glucose should be given intravenously in doses of 10 to 20 g. This is most conveniently administered as 33½ per cent. or even 50 per cent. glucose in a 20 ml. syringe.

✓*Local reactions to insulin.*—A few patients suffer from painful, red, itching bumps, which appear at the site of each insulin injection, and last about 36 hours. They appear to be due to a form of sensitisation. Sometimes they can be avoided by changing to a different brand of the same type of insulin. In rare intractable cases desensitisation may be attempted, but if the claim that they rarely occur with the new Insulin Zinc Suspensions is substantiated, change to one of these will usually be the simplest solution.

✓*Insulin fat atrophy.*—Curious hollows at the sites of injection due to disappearance of subcutaneous fat are sometimes seen in children and adult females, rarely in adult males. They can occasionally be disfiguring. No treatment is constantly effective, though it has been claimed that persistence in injecting the insulin into the tissue at the base of the hollow will cause it to fill up. The simplest course is to advise the patient to use 80 strength insulin and to make injections into the lower abdomen, the buttocks and the tops of the thighs, where loss of subcutaneous fat is unlikely to be noticed and may be welcome.

Management of intercurrent illness.—Many cases of ketosis and coma would be prevented if it were generally realised by both patients and doctors that diabetics with intercurrent illnesses, particularly infections, often need an increase in their insulin dosage. On no account should insulin be discontinued or the dose seriously reduced because the patient is unable to eat his ordinary diet, as this leads to ketosis and coma. If a patient is unable to eat his usual diet on account of an intercurrent illness, he should take his usual dose of insulin (or a larger one) and take the carbohydrate of the diet either in the form of sugar in water or lemonade, or as some kind of carbohydrate in fluid form. This can easily be arranged if it is remembered that 10 g. of carbohydrate can be taken as:

Sugar	2 large lumps or 2 teaspoonfuls.
Glucose	½ oz. or 2 teaspoonfuls.
Orange juice	4 oz.
Milk	7 oz.
Horlicks	}	..	2 heaped teaspoonfuls.
Ovaltine			

Diets for patients on insulin.—The argument between the protagonists of "fixed" and "free" diets is to some extent a matter of words. No one seriously suggests that a diabetic on insulin should be free to gorge on sweets one day and eat almost nothing the next; and no one now attempts to make patients weigh all food eaten. Both accept the need for some degree of control, but differ as to how the control should be exercised. A reasonable compromise is to ask patients to learn to measure their carbohydrate foods by weighing them until they can guess standard 15 or 5 g. portions of carbohydrate foods fairly accurately, and thereafter to weigh them occasionally as a check on their ability to guess. They can thus limit themselves to a prescribed amount of carbohydrate and a prescribed distribution of carbohydrate among the meals for the day without undue hardship. Protein foods and fat are allowed in "average" amounts, though patients should be warned to avoid an excess of fat in view of the probable association between a high fat intake and atherosclerosis.

In arranging a diet for an intelligent and knowledgeable patient, it is usually

enough, therefore, to prescribe the total amount of carbohydrate and how it should be distributed throughout the three or four main meals of the day. Such patients can then select such 15 or 5 g portions of whatever carbohydrate foods they prefer. Less intelligent patients may need to have the exact foods they should take written out for them, as in the following example:

BREAKFAST		CH in grammes
Tea or coffee with milk from allowance		
Breakfast cereal, $\frac{2}{3}$ oz, or porridge made from oats, $\frac{2}{3}$ oz		15
Bacon, egg, fish, etc., an average portion		
Bread, 2 oz (two $\frac{1}{2}$ -in slices off a large loaf)		30
Butter or margarine from allowance		—
		45
		—
MID MORNING		
Tea or coffee with milk from allowance		
1 plain biscuit		5
		—
DINNER		
Meat, fish, rabbit, liver, cheese, etc., an average portion		
Unthickened gravy		
Potato 6 oz, or bread 2 oz		30
Vegetable from Group II, as desired		
Fruit from Group I, 2 portions		10
		—
		40
		—
TEA		
Tea, with milk from allowance		
Bread, 2 oz		30
Butter or margarine from allowance		
Tomato, watercress, cucumber, Marmite (to make sandwiches)		—
		30
		—
SUPPER		
Fish, cheese, meat, egg, bacon, etc		
Salad or vegetable from Group II		
Bread 2 oz, or potato, 6 oz		30
Butter or margarine from allowance		
Fruit, 3 portions or equivalent		15
Tea or coffee, with milk from allowance		
		—
		45
		—
BEDTIME		
Tea or coffee, with milk from allowance		
1 plain biscuit or equivalent		5
		—
Daily allowance of milk = 1 pint		30
Daily allowance of butter or margarine = $1\frac{1}{2}$ oz		—
Total carbohydrate		200 g.

This diet has the carbohydrate *divided more or less* equally throughout the day, as is generally suitable for a patient on a mixture of P.Z.I. and soluble. For other régimes, rearrangement of the carbohydrate would be necessary as indicated in the table. Substitutions can be made *ad lib.* A few examples follow :

SUBSTITUTES FOR 1 oz. BREAD (15 g. CARBOHYDRATE)

Or 3 portions of any fruit or vegetable from Group I.

Milk	10½ oz.	Rice, sago, etc.	} 2 oz.
Orange juice	6 oz.	Cornflakes	
Potato	3 oz.	Oatmeal	
Jam	} ¾ oz.	Quaker oats	
Marmalade, etc.		Vita-Weat biscuits	
Ovaltine		Ryvita biscuits	
Plain biscuits			

The following weighed amounts of these fruits and vegetables may be exchanged for either 1 oz. potato or ½ oz. bread or 3½ oz. milk.

Each portion contains 5 g. CARBOHYDRATE

FRUITS

Group I.

Banana, without skin	} 1 oz.	Apple, raw	} 2 oz.
Grapes		Cherries, raw	
Prunes, stewed		Damsons, raw	
Raspberries, raw	} 3 oz.	Pears, raw	
Strawberries, raw		Plums, raw	
		Orange, without skin	

VEGETABLES

Group I.

Baked beans	} 1 oz.	Peas, fresh	2 oz.
Butter beans, boiled		Carrots, boiled	4 oz.
Peas, tinned			
Potatoes, boiled			

FRUIT AND VEGETABLES

Group II.

An average helping of any of the following fruits or vegetables may be taken in addition to the other foods given on the diet sheet :

ARTICHOKEs	CELERY	MARROW
ASPARAGUS	CUCUMBER	GOOSEBERRIES, stewed without sugar
BROCCOLI	FRENCH BEANS	MUSHROOMS
BRUSSELS SPROUTS	GRAPEFRUIT	OLIVES
CABBAGE	LETTUCE	RADISHES
CAULIFLOWER	LEMON JUICE	RUNNER BEANS
		SPINACH
		TOMATOES
		WATERCRESS

No exact rules can be laid down for the total amount of carbohydrate. This will depend on the age, weight, appetite and habits of the particular patient, and may

vary for an adult by anything from 120 to 350 g or more, which with average amounts of protein and fat will correspond roughly to 1,200 to 3,500 calories. Growing children and adolescents should be given larger amounts of carbohydrate in proportion to their weights than adults. The aim should be to provide a diet which satisfies patients' appetites but keeps them from getting fat.

The distribution of carbohydrate foods in the day varies with different insulin regimes, and may have to be adjusted by a process of trial and error for individual patients. The following table shows some of the properties of different insulins and the kind of distribution of carbohydrate generally found most suitable for the commonly used regimes.

Type of insulin	Strengths available in units per ml	Length of action	Time of maximum effect (when hypoglycæmic attacks are most likely)	When given	Suggested distribution of CII in diet (for total of 200 g per day)					
Soluble	20, 40, 80	Small doses $\frac{1}{2}$ to 6 hours Large doses $\frac{1}{2}$ to 10 or 12 hours	2 to 5 hours after injection 2 to 8 hours after injection	About 20 minutes before breakfast and evening meal	Breakfast	Mid-morning	Lunch	Tea	Evening Meal	Last thing
					65	10	30	20	65	10
P Z I	40, 80	4 to 24 hours or more	Afternoon, evening night or early morning	About 20 minutes before breakfast	40	10	45	45	50	10
Globin	40, 80	2 to 18 hours	Midday or early after noon	About 20 minutes before breakfast	30	10	70	40	40	10
I Z S Lente	40, 80	2-24 hours	Morning or afternoon	About 20 minutes before breakfast	50	10	50	50	30	10
					60	20	50 or 30	30	30	10

Patients with severe diabetes are best admitted to hospital for rapid control. Others can start treatment successfully at home, preferably with the help of a district nurse.

In either case, a patient who is not in ketosis can be placed immediately on the diet considered likely to be suitable for his age and occupation. In hospital rapid control of more severe cases can usually be obtained by starting soluble insulin in doses of from 16 to 24 units three times a day, 20 minutes before the three main meals, and by increasing or decreasing the dose according to the results of urine tests. When satisfactory control has been attained, two doses of soluble insulin or an equivalent single dose of a long-acting insulin may be substituted for three doses of soluble.

In milder cases starting treatment at home, it is usually satisfactory to begin

with a single small dose of a long-acting insulin, and to increase this gradually according to the results of urine tests. It will usually be found satisfactory to start with a dose of 12 or 20 units and to increase this by 4 or 8 units at each visit.

c. Treatment of patients with ketosis.—The treatment of coma is considered under complications. Patients with mild ketosis (positive nitroprusside test, negative ferric chloride test) should have their dose of insulin increased by one-quarter or one-third, and should be seen again within a few days. Patients with severe ketosis (positive nitroprusside and ferric chloride tests), whether new or known diabetics, should be treated vigorously, preferably in hospital.

The ketosis is abolished most rapidly by giving soluble insulin and either glucose or carbohydrate feeds at frequent intervals. In some cases it may be enough to continue with the patient's usual diet and give a dose of soluble insulin before each of the three main meals. In more severe cases the following régime will be found useful:

STAGE I (4-hourly insulin and glucose)

Forty g. of glucose in water or lemonade, with 20 units of soluble insulin subcutaneously every 4 hours. The urine is tested 4-hourly and the insulin dosage increased or decreased as necessary. This is continued until the urine is free from ketone bodies, and vomiting has ceased.

STAGE II (thrice daily insulin and fluid or semi-solid carbohydrate feeds)

Insulin			CH in grammes
	7.30 a.m.		
	8 a.m.	Tea made with milk from allowance.	
		Porridge made from $\frac{2}{3}$ oz. oats or breakfast cereal, $\frac{2}{3}$ oz.	
		Glucose or sugar, 15 g.	30
		Milk from allowance.	
		Orange juice, 6 oz., with glucose, 10 g.	25
			55
	10 a.m.	Lemonade (fresh lemon juice and water), glucose, 10 g.	10
		Cream crackers, $\frac{1}{2}$ oz.	10
			20
	12 noon	Clear soup, meat or yeast extract.	
Insulin	1.30 p.m.		
	2 p.m.	Milk pudding made from :	
		Semolina, rice, sago, tapioca, $\frac{2}{3}$ oz.	15
		Milk from allowance.	
		Glucose or sugar, 15 g.	15
		Orange juice, 6 oz., with glucose, 10 g.	25
			55
	6 p.m.	Tea, with milk from allowance.	
		Cream crackers or water biscuits, 1 oz.	20
		Butter from allowance.	
			20

	Total carbohydrates	240 g

From Stage III the patient can be changed back to his usual diet and insulin regime

SURGICAL OPERATIONS ON DIABETICS *(Emergency operations)*—In an emergency a diabetic patient with glycosuria but without ketosis, can safely be operated on without preliminary treatment. If the patient is found to have a ketosis of any severity (nitroprusside and ferric chloride tests positive), the operation should, if at all possible, be postponed for a few hours while the ketosis is treated vigorously with frequent doses of soluble insulin. The dose must depend on the patient's previous dose, the severity of the ketosis, the degree of urgency and the experience of the physician, but 20 to 40 units of soluble insulin hourly would be safe and suitable for most patients. As such a patient is likely to be severely dehydrated, he should also be given several litres of either half normal saline by mouth or normal saline intravenously. If he has been vomiting the stomach should be washed out before the operation. One of the main difficulties is the diabetic patient who presents in ketosis with symptoms suggesting an abdominal emergency. Patients with ketosis alone may have vomiting, abdominal pain, tenderness, rigidity and a leucocytosis, which improve rapidly when the ketosis is corrected. In doubtful cases the history is of more value than the physical signs. If thirst and polyuria preceded the abdominal symptoms, it is likely that the whole picture is due to diabetic ketosis. If the abdominal symptoms preceded the thirst and polyuria, it is more likely that the ketosis is the result of acute abdominal disease.

(b) *Planned operations*—Diabetic patients should be in hospital for a few days before operation for regulation of the diabetes. Those on a small dose (i.e. under 20 units) of a long acting insulin can remain on this regime. Those on a larger dose should be changed temporarily on to two or three doses of soluble insulin. On the day of the operation, the patient should be given a dose of soluble insulin and a carbohydrate feed 3 to 4 hours before the operation. No rule can be given as to the exact amounts. The dose of soluble insulin may be $\frac{1}{2}$ to $\frac{2}{3}$ the patient's usual morning dose of soluble insulin, reckoned on the basis of control by two daily doses of this type of insulin, 32 units of soluble insulin and 64 g of glucose in water flavoured with orange juice would be average amounts. Hypoglycaemia is a greater danger than hyperglycaemia under the anaesthetic, and this will be avoided if 2 g of glucose are given for every 1 unit of insulin.

With good pre operative treatment of the diabetes the choice of anaesthetic is not particularly important. Ether and chloroform are best avoided. Regional and spinal anaesthetics when practicable are satisfactory, but not by any means essential. Gas and oxygen or intravenous thiopentone followed by cyclopropane and oxygen have given excellent results.

The object in the post operative period is to give carbohydrate either as intravenous 5 per cent glucose or as fluid carbohydrate feeds covered by adequate amounts of soluble insulin, until the patient can return to his normal diet or regime. A ratio

of 1 unit of insulin to 2 g. of glucose will usually be found satisfactory. A minimum of 160 g. of glucose a day, *i.e.* 40 g. and 20 units soluble insulin 6-hourly should be maintained, the amount of insulin being varied according to the results of urine tests. The stage I, II and III diets for the treatment of severe ketosis (p. 435) can be used satisfactorily with or without minor modifications for most such patients.

Pregnancy in diabetics.—Insulin therapy has made pregnancy practically as safe for the diabetic as for the non-diabetic mother, provided she has the benefit of strict and skilled diabetic supervision. It has not, however, done the same for the fœtus, and in general the fœtal loss rate from intra-uterine death, obstetric complications and neonatal death has remained in the region of 40 per cent.

It is known that women who subsequently develop diabetes tend to have large babies, as well as diabetic women; and also that the high fœtal loss rate is evident before the onset of the diabetes, particularly in the last 2 years before this onset. It is also known that diabetic women show an undue incidence of hydramnios and toxæmia of pregnancy. Diabetic babies, apart from their size, usually have a tough leathery skin with coarse features. There is œdema of the skin and subcutaneous tissues. The heart, liver and spleen may be pathologically enlarged, and there is a high incidence of congenital abnormalities. The babies are usually slow and lethargic and subject to cyanotic attacks in the first few days of life. It seems likely that such babies may be hypoglycæmic shortly after birth, but it is unlikely that this accounts for the high early neonatal death rate. In practice, oxygen seems more important than glucose. Babies that survive this period are often difficult to feed and rear at first, but then develop normally.

It seems likely that the abnormal features of diabetic pregnancies are associated with a complicated hormonal disturbance, in which, amongst other things, the placenta fails to utilise chorionic gonadotrophin in the production of œstrogen and progesterone, particularly in those women who develop toxæmia. It is uncertain, however, whether the hormonal upset is the result or the cause of the abnormal pregnancy states. The whole subject is still under investigation, and substitution therapy with synthetic œstrogens and progesterone must be regarded as experimental.

There is no doubt that strict control of the diabetes is essential. The insulin requirements of pregnant diabetic women undergo variations, and usually increase considerably as the pregnancy proceeds. Further, the renal threshold commonly falls between the third and fifth month, which makes good control more difficult. Such women should be under close supervision and should be seen at short intervals. Those on large single doses of a long-acting insulin should be changed to two or three doses of soluble insulin a day. When control is difficult, such patients may have to be admitted to hospital once or twice during the pregnancy, and should all be admitted by the thirty-second or thirty-third week. Most authorities now favour Cæsarean section at or about the thirty-sixth week. This reduces the incidence of toxæmias and fœtal deaths, which are commonest in the last week or two of pregnancy, and avoids prolonged labour and obstetrical difficulties, but is open to the objection that it may increase the neonatal death rate by adding prematurity to the babies' difficulties. There is often a rapid fall in the mother's insulin requirements early in the puerperium.

Complications.—Diabetics appear more liable than normal persons to suffer from infections (particularly staphylococcal skin infections) pulmonary tuberculosis and urinary infections (commoner in women), from cataracts and from various forms of arterial degeneration. Diabetic ketosis and coma, nephropathy, neuropathy, retinopathy and a rare form of "true diabetic cataract" may be regarded as true complications of diabetes.

Diabetes and pulmonary tuberculosis.—Diabetics should have their chests radiographed as a yearly routine, and pulmonary tuberculosis should always be remembered as a possible cause of unexplained loss of weight or deterioration in diabetic

control. Patients with diabetes and active pulmonary tuberculosis should be treated with a liberal high carbohydrate diet and enough insulin to ensure good control. It is often necessary to give such patients two or three injections of soluble insulin a day, and to vary the dose frequently to obtain good control. It has been claimed also that isoniazid impairs carbohydrate tolerance and may increase insulin requirements. There is unfortunately a shortage of suitable accommodation where patients may get the most expert control of both their tuberculosis and their diabetes.

(c) *Arteriosclerosis and obliterative arterial disease in the legs.*—It is probable that diabetics are more liable than non-diabetics to all forms of arterial degeneration, including coronary and cerebral artery disease and obliterative arterial disease in the legs. The reason is unknown, as is the pathogenesis of arteriosclerosis in general. It has been suggested that arteriosclerosis is an integral and inevitable part of certain forms of diabetes, but some physicians with great experience believe that its onset is delayed by strict treatment. Obesity appears to be a factor, and this is an additional reason for encouraging obese diabetics to reduce their weight.

Obliterative arterial disease in the legs presents in diabetics more often as gangrene than as intermittent claudication. The reverse is the case in non-diabetics. Arteriography shows that this is due to the fact that the obstruction in the arteries of diabetics is usually in peripheral vessels, rather than in the femorals and popliteals. The incidence is related to age rather than to the severity or duration of the diabetes.

Many of the complications of poor circulation in the feet, infected corns, calluses and ulcers—all of which may lead to gangrene—can be prevented by foot precautions. Older diabetics should be taught to wash, dry and powder their feet daily. Drying and powdering between the toes is particularly important to prevent fungus infestations, which may be the start of septic infection and gangrene. Toe-nails should be cut carefully straight across by someone with good eyesight, and corns should be treated cautiously by experienced chiropodists.

The treatment of intermittent claudication does not differ from that in non-diabetics, and drugs are equally ineffective. Good control of the diabetes and the use of antibiotics has robbed diabetic gangrene of its worst terrors. Patients with localised areas of gangrene, usually of a toe, should be in bed with a cradle over the foot, which should be only lightly covered. The diabetes should be well controlled and antibiotics should be used *secundum artem* to control infection. The gangrenous area can be kept clean and dry with spirit or covered with tulle gras. If a radiograph shows there is no necrosis of bone, the most conservative surgery, merely "nibbling" at the gangrenous area, will produce excellent results. If necrosis of bone is present, the affected digit or portion of the foot should be amputated. Mid-thigh amputation is only necessary in a small minority of patients, when all more conservative measures have failed.

(d) *Diabetic coma.*—Diabetic coma is one of the most serious of medical emergencies and one with a considerable mortality, unless it receives skilled and speedy treatment and constant attention. It cannot be emphasised too often, therefore, that most cases of diabetic coma are preventable. The exceptions are occasional patients with undiagnosed diabetes, who present in coma without ever having consulted a doctor, and a few patients who are either too stupid, too unco-operative or too ill-disciplined to learn to avoid it, however much effort is expended on their education. Coma can occur if a patient has an infection or if he stops taking insulin, but it occurs most commonly from a combination of these causes. A patient with an infection cannot eat his normal diet, and therefore stops taking his insulin. Many cases of coma would be prevented if both doctors and patients understood how to deal with infections and intercurrent illnesses as outlined on p. 431.

The main clinical features of diabetic coma are listed in the following table and contrasted with those of hypoglycaemic coma, though the big difficulty in practice

is usually not in diagnosing between these conditions, but between diabetic coma and other varieties of coma occurring in a diabetic

	<i>Diabetic</i>	<i>Hypoglycæmic</i>
- History	Missed insulin	Missed meal
- Onset	Infection, etc	Unusual exertion, etc
- Skin	Slow	Rapid
- Tongue	Dry	Sweating
- Pulse	Dry	Moist
- B P	Small volume	Bounding
- Breath	Reduced	Normal or raised
- Eyeball tension	May be acetone	No acetone.
- Respiration	Reduced	Normal
Urine	Deep and slow 'air hunger'	Rapid and shallow
	Sugar	May be sugar
	Ketosis ++	No ketones
Blood sugar	Usually 400 mg per cent or over	Less than 60 mg per cent
Plasma CO ₂	Diminished	Normal

Diabetic coma is a major emergency and should if at all possible, be treated in a hospital with facilities for urgent biochemical investigations but treatment should be begun without waiting for the results of such investigations. If the practitioner is certain of the diagnosis of severe diabetic coma he should give 100 units of soluble insulin before sending the patient to hospital.

Wherever the patient is to be treated he should be placed in a warmed bed and a specimen of urine should be obtained immediately by catheter. If blood sugar estimations are not available the catheter should be left in position, so that regular specimens can be obtained.

Treatment consists in

1 Adequate doses of insulin. Give 100 units (80 i.m. and 20 i.v.) as soon as diagnosis is made. Take blood for blood sugar. If this is over 600 mg per cent. give further 100 units by same routes. Repeat blood sugar at 1½ hour intervals and adjust further insulin dosage accordingly. If no facilities for blood sugars give 100 units and then 40 units hourly. Amount of sugar in urine gives no indication of blood sugar until this falls below 300 mg per cent.

2 Replace water and salt deficiency. Set up intravenous drip and give normal saline or better, saline lactate solution (Nabarro) consisting of

Sodium chloride	5.85 g
Sodium lactate	3.36 g
Distilled water to	1 litre

Give 1 litre in 15 minutes a second in the first hour and then continue more slowly 6 or 8 litres of parenteral fluid in the first 12 hours or so is not an excessive amount. The blood pressure should be taken half hourly and if this falls or if other signs of circulatory collapse appear, blood (or dextran or plasma) should be given in place of the saline or saline lactate solution.

3 Wash out stomach and evacuate colon.

Patients in diabetic coma often have dilated stomachs containing quantities of fluid which may be regurgitated and inhaled. The stomach should therefore be evacuated by stomach tube and washed out with warm water, and the tube may be left in position to allow of repeated gastric suction. Patients are also sometimes extremely constipated with palpable scybala in the colon. As soon as the patient is out of danger from ketosis and dehydration olive oil should be given per rectum and followed by plain water enemata.

4. Look for and treat any infections (boils, injection abscesses, pulmonary tuberculosis, etc.) which may be present. Penicillin 500,000 units b d should be given prophylactically even if no infection is found.

5. When the blood sugar begins to fall, or if blood sugars are not available, when the sugar in the urine diminishes, substitute 5 per cent glucose for the saline or saline lactate solution, and give at the rate of 1 litre every 4 to 6 hours. Once the patient is conscious and the blood sugar is normal, give sips of water, followed by milk and fluid carbohydrate feeds. Transition to a normal diet can be conveniently planned by using the diets provided for the treatment of severe ketosis (p. 435).

It is now known that once ketosis is controlled, the greatest danger is deficiency of potassium. Under ideal conditions, intravenous 5 per cent glucose should be replaced by a solution containing glucose, potassium and other electrolytes, provided always the urinary output is normal. When such a solution is not available, 5 per cent glucose should be used and potassium should be given by mouth as soon as possible. This can be given as potassium citrate 4 g = 60 grains t d s or a drink containing glucose 50 g, dibasic potassium phosphate 2 g in 500 ml water flavoured with orange juice. Up to 2 litres of this mixture should be given daily for 2 or more days or until the patient is taking a full diet. Patients who have been in deep coma should not be allowed to sit up or otherwise exert themselves for several days.

(*) Eye complications—Impairment of vision in diabetics may be due to temporary changes in refraction, associated with change in water balance, to lenticular opacities or to retinopathy. Slowly progressive impairment of vision is more often due to cataracts than to retinopathy. Rapid loss of vision, fortunately rare but sometimes leading to complete blindness, is usually due to advanced retinal disease.

Transient changes in refraction—Blurring of distant vision from myopia may occur in untreated diabetics, and the sudden onset of myopia in any patient should raise a suspicion of diabetes and lead to testing of the urine. But visual symptoms of this kind are commonly encountered shortly after starting treatment with insulin due to changes in hydration of the lens. The patient should be dissuaded from seeking glasses or new glasses until it is seen whether the blurring disappears after the diabetes has been satisfactorily controlled for 4 weeks.

Lenticular opacities—Two kinds of cataract occur in diabetics. It is usually stated that ordinary senile cataract is commoner in diabetics than in the general population, though this has been denied by one or two observers of large series, who claim that if sufficiently careful examination is made, the incidence is about equal. The treatment is the same as in non-diabetics. "True diabetic" cataract or "snow-flake" cataract is very much rarer, and occurs in adolescence or early adult life. It is said that it is reversible and may improve or even disappear with strict treatment of the diabetes.

Retinopathy—Diabetic retinopathy is commoner in younger patients than is generally realised. In older patients there is often a mixture of diabetic and hypertensive changes.

The earliest and only specifically diabetic change is the appearance of capillary micro aneurysms, tiny sharply defined rounded spots, venous in colour and much smaller than most hemorrhages. These are aneurysms of communicating branches between the capillaries of different layers of the retina. If carefully looked for, they can sometimes be seen as the only change in the retina of quite young patients who have had diabetes for a number of years. The later changes are round "deep" hemorrhages and small, irregularly shaped, yellowish-white, "hard" or "waxy" exudates. "Fluffy" or "cotton wool" exudates are occasionally also seen, even in the absence of hypertension.

Some diabetics also show changes in the veins which may be proliferative or non proliferative. In the latter, the veins in some areas may be "beaded", or overfilled and tortuous, or may be thrown into loops and coils. In the proliferative form,

"retinitis proliferans", new vessels are formed, which may in time grow into the vitreous. If vitreous hæmorrhages then occur, organisation of the clot may lead to retinal detachment, retinitis proliferans with hæmorrhages and retinal detachment being the usual cause of sudden and rapid deterioration of vision in diabetics. Such patients are also liable to glaucoma.

In older patients, the picture of diabetic retinopathy is often complicated by the addition of hypertensive changes, narrowing of the arterioles, superficial flame-shaped hæmorrhages and "cotton wool" exudates. It is likely that good control of diabetes delays the onset of retinopathy, and it has been claimed that the earliest changes in young diabetics are reversible by strict treatment. Once retinopathy has become established, stricter treatment of the diabetes makes disappointingly little difference.

Retinopathy is probably part of a generalised vascular process, since capillary fragility as measured in the arms is increased in diabetics with retinopathy. There is no evidence that drugs which may reduce capillary fragility, such as ascorbic acid, vitamin P and rutin, have any effect on the course of diabetic retinopathy.

Nephropathy—If the urine of diabetics is tested for albumin as a routine at every visit, a surprising number are found to have intermittent or continuous albuminuria. This may be due to cystitis, acute or chronic, pyelonephritis, nephritis, arteriosclerotic kidney, heart failure and so on. Symptomless urinary infections are common, particularly in elderly females.

In 1934 Kummelstiel and Wilson described an histological picture in the kidneys characterised by the presence of discrete islands or nodules of hyaline material in the glomeruli. It is probable that this picture of "intercapillary glomerulosclerosis", at least in its severe forms, is confined to the kidneys of diabetics, and is associated with a recognisable clinical picture. This has come to be known as diabetic nephropathy and is one of the diabetic's most serious long term risks. Patients are usually middle-aged or over, more often female than male, with a history of diabetes for many years. Intermittent or continuous albuminuria which may last several years without other signs, is followed by slight or massive œdema of the dependent parts, severe hypertension and retinopathy, which may be severe and lead to failing vision. Characteristically, the insulin requirements fall as the renal disease advances. When the œdema is gross, it is associated with low plasma protein, and can sometimes be controlled to some extent by a high protein, low sodium diet. Otherwise treatment has no effect, and death from renal failure, cardiac failure or cerebral hæmorrhage occurs up to about 10 years from the first manifestation of a renal complication. It seems likely that intercapillary glomerulosclerosis and retinopathy are both manifestations of a single vascular degenerative process. It is probable that really good control of the diabetes delays or prevents the onset of these complications, but once they are established, control of the diabetes does not prevent their progressive course.

Neuropathy—The manifestations are protean. Absence of the ankle jerks with diminution or absence of the knee jerks, sometimes associated with some loss of vibration and deep pressure sensation in the legs, but without subjective complaints, is common in those who have had diabetes for some years. In addition, various pains and paresthesiæ, usually in the legs, may occur with or without objective sensory changes. Occasionally severe burning pain in the feet, worse or almost intolerable at night, may be complained of. In rare instances the neuropathy takes the form of an acute neurological illness with gross weakness of the legs, particularly of the quadriceps, so that patients may have to go upstairs on all fours. The legs show weakness, wasting, flaccidity, loss of tendon jerks and various degrees of sensory loss. In some of these patients the pupils are irregular and react poorly to light, a neuropathic bladder may occur, and the cerebrospinal fluid protein is raised, a syndrome which has been called "diabetic pseudo-tabes". Another curious feature is nocturnal diarrhœa, which may be controlled by injections of liver extract. Isolated cranial nerve palsies which recover spontaneously are also seen. Impotence

can occur, but in general, impotence in diabetics is due more often to anxiety than to neuropathy

Diabetic neuropathies usually supervene in patients whose diabetes is badly controlled and are the one form of complication in which strict treatment will bring about a remarkable improvement

SPONTANEOUS HYPOGLYCÆMIA

Mild hypoglycæmia some time after meals or in association with emotional upsets is fairly common in unstable asthenic individuals. Such people discover that carbohydrate relieves their symptoms. Ingestion of carbohydrate then leads to a rise in blood sugar followed by a compensatory overproduction of insulin, a fall in blood sugar and return of hypoglycæmic symptoms, further ingestion of carbohydrate and so on. A similar mechanism is thought to operate in the post-gastrectomy dumping syndrome (p. 587) in which hypoglycæmic symptoms may occur shortly after meals. Both these conditions can often be relieved by a high protein, low carbohydrate diet, avoiding particularly sugar and easily assimilable forms of carbohydrate.

By comparison other causes of spontaneous hypoglycæmia are excessively rare. It is found as a curiosity in hypopituitarism and hypocortico adrenalism (failure of pituitary-adrenal blood sugar raising mechanism) in advanced liver disease (failure to store glycogen), von Gierke's disease (abnormal fixation of liver glycogen) possibly in cases of very severe renal glycosuria and finally in hyperinsulinism. It is important that hyperinsulinism should be diagnosed since a progressive and fatal condition can then sometimes be completely relieved by surgery.

HYPERINSULINISM

Ætiology and Pathology—Hyperinsulinism is usually due to a small islet celled adenoma (1 to 2 cm diam), which probably has no predilection for any part of the pancreas, but is more likely to be found when it is in the body or tail. Occasionally two or three such adenomata are present. More rarely the tumour is a carcinoma and metastasises to the adjacent lymph glands and the liver. Occasional cases have been attributed to generalised hyperplasia of islet cell tissue.

Symptoms—The main difficulty in diagnosis is that patients with attacks of the kind of symptoms usually associated with hypoglycæmia (apprehension, tachycardia, shakiness, sweating, weakness and fainting) nearly always turn out to have the functional hypoglycæmia mentioned above, whereas patients with islet cell tumours are apt to present with bizarre attacks or peculiar neuro-psychiatric manifestations, which are easily misdiagnosed as hysteria, epilepsy, alcoholism, cerebral tumour (particularly hypothalamic tumour) or psychosis. It is therefore in neurological, neuro-surgical and psychiatric departments and in the observation wards of mental hospitals that such patients are likely to be found. This diagnosis should be considered in any peculiar neuro-psychiatric illness, particularly if associated in the earlier stages with episodes of change of mood or loss of consciousness, in which sweating is noticed. Later convulsions and irreversible neurological changes or psychosis may be added.

Diagnosis—The diagnosis of hyperinsulinism is confirmed by the finding of a blood sugar of less than 50 mg per 100 ml in an attack, and by prompt recovery, at least in the early stages, on administration of large quantities of glucose intravenously. It is, however, important to remember that when a patient has been comatose from this cause for some time, intravenous glucose may not cause rapid improvement, and a random blood sugar may not always be at a hypoglycæmic level.

Treatment.—The immediate treatment in an attack is the administration of intravenous glucose as for insulin hypoglycæmia (p. 431). Many insulin-secreting adenomata have now been successfully removed, with complete relief of symptoms. A second operation has occasionally been necessary when more than one adenoma was present. When the diagnosis of spontaneous hypoglycæmia is certain and no tumour can be found in the pancreas, it is usual to perform a subtotal pancreatectomy. No treatment is possible for malignant tumours with metastases, for alloxan which destroys normal islet cells, does not appear to affect malignant ones.

RICHARD R. BOMFORD.

LÆVULOSURIA

Lævulosuria is a sign of some derangement of the liver and should direct attention to that organ. Slight reduction of carbohydrates and of fruits is usually sufficient to check it.

GALACTOSURIA

Galactosuria has probably been confused with glycogen disease but paper chromatography of the urine has made it possible to distinguish between them. The child has an inborn inability to metabolise lactose and on a milk diet develops a large liver (with or without jaundice) going on to cirrhosis. Cataract and mental defect also occur. Elimination of all lactose from the diet leads to great clinical improvement, but whether all the complications can thus be prevented remains to be seen.

ALAN MONCRIEFF.

LACTOSURIA

This occurs (1) during lactation, (2) when suckling suddenly ceases and (3) in breast-fed infants with enteritis.

PENTOSURIA

This is a rare occurrence. Many of the patients are Jews. Of 7 cases 3 were Jews, 2 Greeks and 2 English (Cambridge).

GOUT

A disease in which there is a disturbance of purine metabolism and an increase of uric acid in the blood. The clinical sign is an attack of acute arthritis with a deposition of sodium biurate in and about the joints.

Ætiology.—*Predisposing causes.*—Gout is much commoner among certain races, e.g. the English and German. It is very uncommon among native races. It does not follow, however, that this is a racial peculiarity. It is much commoner in temperate than in tropical climates, but it is unlikely that the climate plays any part in the causation of the disease. The evidence in favour of gout being an hereditary disease is very strong, as a history of a gouty ancestry can be obtained in 50 to 80 per cent. of the cases. A history of gout in the family was obtained in 75 per cent. of well-to-do patients and in 50 per cent. of hospital patients (A. B. Garrod). This evidence suggests that the disease is chiefly hereditary but may be acquired. It is not the disease which is inherited, but only the predisposition to it, and the disease may lie latent until it is evoked by other causes (Llewellyn). It is a disease of middle life—between the ages of 35 and 50—but it may occur much younger, even in school-boys who have a strong hereditary taint. The malady is very much more common in men than in women. Women form only 5 to 20 per cent. of the patients in most statistical tables and these are practically all of the post-menopausal age-group.

Exciting causes.—Food plays a part in the causation of the disease, but it is rather the quality than the quantity which matters. Meat and the purine bodies in tea, etc.,

probably have little effect, but sweetbreads, liver, kidneys, fish roes, tripe may be actively harmful. Spirits have little effect, and gout was almost unknown in Scotland when it was common in England. Beer is much more potent and is probably partly responsible for the prevalence of gout in England and Germany. The strong wines like port and sherry, and the red wines such as Burgundy and claret, are also probably responsible for evoking some gout among the well-to-do classes, and champagne has a bad reputation. The light white wines like Graves and hock and cider are less evil. Gout was formerly very common among lead workers in England, and the cessation of serious poisoning may be another cause for the decrease in gout. Trauma plays a great part in the causation of the acute attack. The big toe may be affected so frequently because of the pressure of the boot. An injured joint may be the seat of the first attack of gout. Syringing the ear of a gouty patient for cerumen was followed by an acute attack in the external auditory meatus (A. E. Garrod). Local sources of infection are very common among gouty patients, e.g. septic gums and tonsils.

Physiology and Pathology.—The fact that sodium biurate was deposited in and around the joints suggested that uric acid played an essential part in the causation of gout. After A. B. Garrod (1848) had demonstrated by means of his thread test that the blood of gouty patients contained uric acid in abnormal qualities, the hypothesis seemed to be proved. The problem is, however, not so simple as was thought at first.

The uric acid which is excreted in the urine of healthy people on an ordinary mixed diet comes from two sources, exogenous and endogenous. When all the exogenous sources of uric acid, e.g. meat, fish, sweetbread, tea and coffee, etc., are removed from the diet the output sinks to a level of 0.5 to 0.7 g. per day. The amount is fairly constant for each individual. If all proteins are removed from the diet, the endogenous uric acid output falls to a lower level than before (Folin). The removal of carbohydrates and a reduction of the caloric value of the diet also cause a decrease in the endogenous uric acid output to the lower level (Graham and Poulton). The endogenous uric acid output is believed to come from the breakdown of the cell nuclei of the body, i.e. wear-and-tear, but it can also be synthesised from histidine and arginine (Hopkins and Ackroyd). When the exogenous purines are eaten, or when uric acid is injected, there is an increase in the uric acid output, but the whole of the uric acid is not excreted in one day. If cinchophen is given at the same time, the excretion-rate of the uric acid is increased.

The blood always contains uric acid, and the limits of normal variation in health are 1 to 3 mg. per 100 ml. The total uric acid in the blood of a man weighing 10 st. 3 lb. or 65 kg. would be 50 to 150 mg., assuming that the blood constitutes $\frac{1}{13}$ of the body weight, i.e. 5000 ml.

In cases of gout there is usually a considerable increase in the amount of uric acid in the blood. Before an attack the blood may contain 4 to 6 mg. of uric acid per cent., though occasionally between the attacks there may be no increase. The uric acid may also be increased in some people who have never had gout; as, in leukaemia, where there is a great destruction of leucocytes, and in cases of renal failure. The increase in the uric acid in the blood is, therefore, not pathognomonic of gout, although it is extremely suggestive of it.

In gout the output of uric acid varies widely. It may be quite small in amount, less than 0.2 g. per day, or it may be equal to that excreted by healthy people. Before the attack of gout it is usually very small in amount, but the paroxysm always causes a great increase in the output for a few days only. When purine bodies are eaten by a gouty patient, or if uric acid is injected, there is great delay in the excretion of uric acid. If cinchophen is given at the same time, the uric acid is excreted much more quickly. The diminution in the uric acid output may be due to an increased destruction in the body or to its retention by the kidneys. There is no evidence of increased destruction in the body, as the blood of a patient before an attack may contain 4 to

6 mg. of uric acid per 100 ml. This suggests that the uric acid is retained by the kidneys. When cinchophen is given to a patient whose blood contains 4 to 5 mg. per 100 ml. uric acid there is a great increase in the uric acid output and a decrease in the uric acid in the blood (Folin and Lyman). The "extra" uric acid excreted in 6 days was 1.9 g., while the blood uric acid decreased from 4.5 mg. to 2.9 mg. per cent. The "extra" uric acid must come from the uric acid "pool" in the body, as the blood does not contain enough uric acid (Graham).

The evidence points to the view that although gout cannot exist in the absence of excess of uric acid in the blood yet uric acid is not the cause of gout.

The essential change is the deposition of uric acid as sodium biurate in the joints. The sodium biurate appears to be plastered over the surface of the cartilage, but on microscopical examination it is seen that there is a layer of cartilage over the deposit, which is always interstitial. The deposits may be quite small or enormous. In severe cases the structure of the bones is destroyed and replaced by sodium biurate. The ligaments, tendon sheaths and bursæ are also infiltrated. The big toe joints may contain sodium biurate, although the patient has never had an acute attack of gout (Norman Moore). The skin covering a tophaceous deposit may ulcerate and break down, and small masses of sodium biurate may be discharged (chalky gout).

Tophi.—Sodium biurate is also deposited in the cartilage of the ear, especially in the outer margin of the pinna. The tophi appear as white nodules from which uric acid crystals can be recovered. They also give the murexide test and a blue colour with Folin's phospho-tungstic reagent.

The kidneys.—An uratic deposit may occur in the pyramids. Norman Moore found it in 12 out of 80 cases. Well-marked changes of chronic interstitial nephritis are often found.

dyspnœa, delirium and coma, but these are probably due to a coincident uræmia. Phlebitis of the veins of the limb may be a complication of an acute attack.

After the attack, whether as the result of illness or as a consequence of the simple living which the patient has endured, the general health of the patient is much improved. The attack usually occurs in the spring and autumn. The second attack may follow at once, or may be delayed for many years.

Chronic gout.—After several attacks, especially if badly treated, the joint may not recover completely. The deposits of urates occur in the ligament and capsule, as well as in the articular cartilages and bones. The joint, therefore, becomes swollen and irregular in its shape. The urate is especially deposited in the bursæ about the joints. In the advanced stages the skin over the uratic deposits breaks down and masses of chalky material are extruded, and the wounds heal with difficulty. The general health of the patient suffers after several attacks and does not recover completely. Dyspepsia is complained of, and the patient may show signs of high blood pressure and arterial disease. The urine is increased in amount, and may contain albumin and casts.

Irregular gout.—Almost any symptom or physical sign which occurred in a person who was of a gouty disposition was formerly ascribed to gout. Cutaneous eruptions, such as eczema, gastro-intestinal disorders, cardio-vascular symptoms and pericarditis, headache, migraine and neuralgia, were all thought to be gouty. A gouty patient may develop any of these diseases, but the belief that there is a general type due to gout is now regarded as unfounded. The urine is usually acid, and on cooling often deposits uric acid crystals. This does not mean that there is an excess of uric acid in the urine, but that the urine is too acid to keep it in solution. On heating the urine the urates are re-dissolved. Gouty persons may suffer from calculi. Glycosuria occurs in some cases, but usually responds readily to treatment. Albuminuria and casts are present when the kidneys are also affected. Elderly persons often suffer from chronic bronchitis. Gout has been accused of rendering patients more disposed to iritis, retinitis and glaucoma. It is possible that iritis and retinitis can have a gouty basis though they may arise independently.

Diagnosis.—The diagnosis in a case of classical gout, with recurring attacks of arthritis in the toe or tarsus, is easy, especially if the patient comes of a gouty stock or indulges in good living. The joints of the hands affected are usually asymmetrical in shape and in distribution unlike those of rheumatoid arthritis. The presence of tophi is proof positive that the patient is a subject of gout. Tophi must be distinguished from Woolner's tip, fibroid nodules and sebaceous cysts, and in cases of doubt an examination should be made for the crystals of sodium biurate with the microscope, and for uric acid with the murexide test or Folin's phosphotungstic reagent. The blood uric acid should be estimated in all cases of doubt, and if more than 3 mg. per cent. is found the case is probably one of gout, it may be normal in amount just after an acute attack. It must be remembered, however, that the uric acid in the blood is increased in cases of chronic interstitial nephritis. While it is certain that gout does not occur in the absence of an increase of uric acid in the blood, the presence of excess of uric acid in the blood does not exclude the presence of other diseases.

Classical gout is much less common than it was, and the modern tendency is to overlook the disease. In the severe cases, in which the joints are severely damaged, the radiographic appearances are very striking. There are dark "punched-out" areas, where the sodium biurate is deposited in large amounts, replacing bone or cartilage, since sodium biurate is not opaque, like the calcium ion. In the less severe cases there may be—(1) lifting at the articular margins, (2) a localised atrophy of the bone; (3) a narrowing of the joint space.

Prognosis.—If a patient has once had an attack of gout he will always be liable to another attack, unless he alters his way of life. The frequency and severity of the

attacks can be modified by treatment. The prospect of long life depends upon the state of the heart, arteries and kidneys.

Treatment.—Dietetic.—In perhaps no other disease have a greater number of dietetic fads been recommended. The total quantity of the food should be kept within reasonable limits, and civic dinners should be avoided. The meals should be simple but attractive. There is little difference between the different kinds of meat, except that for those who have dyspepsia chicken is more easily tolerated than beef and mutton. There is no need to deprive the patient of sugar or of starchy food, but they should be eaten in moderation. The same is true of fat. Some gouty persons are much too stout, and a reduction of weight is beneficial.

All protein foods contain purine, but their content varies widely. Liver, kidneys and sweetbread are rich in purines, and these should be avoided, as the uric acid which is formed from the breakdown of the purine is excreted more slowly by the gouty patient than it is in health. Attacks of gout have followed very quickly after eating sweetbreads and after the administration of purines for experimental purposes. The fruits and vegetables which contain an excess of oxalates, *i.e.* strawberries, rhubarb, spinach and asparagus, should be forbidden if oxaluria is present.

Heavy beers, strong wines like port and sherry, all red and white wines and also champagne, should generally be forbidden for gouty patients. If drunk in moderate amount and well diluted, whisky is probably the least harmful beverage. Mineral waters may be of considerable benefit to gouty persons. Their mode of action is uncertain, but is probably due not so much to the ingredients of the waters as to the amount of water drunk, the simple and restricted diet, and the regular and supervised life which the patient leads at a spa. Hot baths and douches are of assistance in aiding the recovery of stiff joints. The waters of Buxton and Bath in England, Vichy, Aix-les-Bains and Contrexéville in France, Wildbad and Homburg in Germany, and Saratoga, Bedford and White Sulphur in America, are the best known.

Local.—During the acute attack the joint should be covered with cotton-wool, placed on a pillow, and the bedclothes raised by means of a cradle. A solution of cold B.P., *lotio plumbi c. opio*, should be applied every 4 hours.

Internal.—Acute attack.—Colchicum is usually specific, the pain is quickly relieved and the redness of the skin and swelling of the joint subside. The active principle colchicine is generally prescribed as a pill containing 0.5 mg. (gr. 1/120) of the alkaloid. One of these should be taken every 1 or 2 hours until pain is relieved, followed by a maintenance dose of 1 pill 3 times a day for a week or so. Symptoms of intolerance to colchicine take the form of nausea and diarrhoea, and usually the dose has been reduced before they become severe. Alternatively, they will respond to mixtures containing bismuth carbonate and tincture of opium. The total amount of colchicine required to abort an acute attack will vary between 4 and 8 mg.

Corticotrophin (A.C.T.H.) is also effective in the acute attack, but unless colchicine is given in addition, relapse may occur when the hormone is discontinued. Phenylbutazone has also been used, but the daily dose should not exceed 800 mg. because of the danger of toxic side effects.

Chronic Gout.—Sodium salicylate, cinchophen and probenecid are effective uric acid eliminants and when given continuously and in adequate doses may reduce the frequency and severity of the acute attacks. Sodium salicylate gr. 60 to 140 daily is combined with an equal quantity of sodium bicarbonate. The usual dose of probenecid is 2 g. daily and it can safely be given for long periods of time. Cinchophen is now best avoided because of its toxicity.

The general health of the patient must be attended to and all causes of sepsis removed. Radiant heat and massage are very useful for restoring the movement of a crippled joint once it is no longer the seat of acute or subacute inflammation.

OBESITY

Obesity is a state in which there is an abnormally great amount of neutral fat in the fat storage depots of the body.

The tendency to become obese affects members of certain races more than others, and a tendency to obesity is found to run in families; it is difficult, however, to determine the relative importance of heredity and of feeding habits in these instances. Obesity tends to develop in both men and women in middle age and in women it frequently begins after childbirth.

The fact that fat is being deposited without a corresponding decrease in other tissues indicates that more calories are being ingested than are converted to heat and are lost in the urine and faeces as organic compounds. Obese people in general have a somewhat higher metabolic rate than thin people of the same height, and there is no evidence that any mechanism exists whereby excessive calories may, in thin persons stimulate metabolism so that they are eliminated as heat. It seems that appetite is the only mechanism whereby the caloric balance is regulated, and thus the crucial factor in obese people seems to lie in a discrepancy between appetite and caloric need.

In clinical practice obese patients not infrequently deny having abnormal appetites and it seems probable that they live in a state of caloric equilibrium, regulated by appetite, only when the body is loaded with excessive adipose tissue. An experimental counterpart is found in animals with hypothalamic lesions. As soon as the lesion has been inflicted the appetite becomes voracious, but this diminishes when the animal has become grossly obese.

Although, as has been pointed out, caloric intake in excess of requirements always occurs during the development of obesity, the reasons for the disparity are not known. Presumably in a few patients, who, for example, become obese after encephalitis, the situation is similar to that of the experimental animals, the damage to the hypothalamus occurring during the infection. In most, however, it is probable that the eating habits developed during youth are carried on into middle age when energy expenditure has become diminished. Psychological disturbances may produce either diminished or increased food intake; in the latter case the gratification derived from the food takes the place of other unsatisfied emotions. Endocrine abnormalities are sometimes associated with increased weight. Hypothyroidism, for example, lowers the basal metabolic rate usually more than the concomitant decrease in appetite. Hypogonadism also is very prone to produce extra fat deposits particularly in the breasts, abdomen, hips and thighs, and it seems possible that the obesity associated with mild degrees of anterior pituitary hypofunction may well be associated with the resulting hypogonadism. Increased activity of the adrenal cortex, whether primary or as a result of stimulation by pituitary hormones, frequently results in obesity. In Cushing's syndrome, where the main excess secretion consists of glucocorticoids, the fat is deposited on the face, neck and trunk, the limbs being relatively spared. In patients with attacks of hypoglycaemia, whether spontaneous or induced in diabetics by too much insulin, the appetite is unduly stimulated and there is a tendency to develop obesity. Finally, the onset of obesity is particularly common at puberty, at the menopause and in women after childbirth. In cases such as these there is presumably some underlying endocrine abnormality which ultimately results in a greater caloric intake than expenditure.

Obesity is one of the main causes of ill-health in most civilised countries. The expectation of life is much shorter than for individuals of normal weight and the incidence of most diseases is greater in the obese than in the normal. Very roughly, the expectation of life decreases by 1 per cent. below the normal for every 1 lb. weight above normal. Obesity appears to be a particularly striking predisposing factor in diabetes mellitus and in cardio-vascular disorders. The death rate from diabetes mellitus is about 250 per cent. more in obese than in normal people and the

rate from cardio-vascular diseases is some 60 to 70 per cent. greater in the obese than in the normal.

Symptoms of obesity.—General lassitude and weariness, dyspnoea on exertion, aches and pains, particularly in the knees and lumbar spine, maceration and infection of the skin, and sometimes œdema of the ankles, are the main complaints of the obese. In addition, however, there may be symptoms associated with hypertension or diabetes mellitus, conditions closely associated with the obesity itself.

The pain in the knees and back is not surprising when one considers the extra weight which has to be carried, 4 or 5 stones (56 to 70 lb.) being not at all uncommon. This alone will tend to produce dyspnoea, but the position is aggravated by the extra blood flow required through the adipose tissue—it has been estimated that there are about 25 miles of blood vessels in every 30 lb. of adipose tissue. This extra strain on the cardio-vascular system is probably one of the reasons why obese people are relatively poor operative risks, and why they do not stand infections such as pneumonia at all well.

Treatment.—There are two main factors to be considered, (1) to correct any obvious underlying cause and (2) to restrict the daily calorie intake below the daily caloric requirements.

When there is any obvious endocrine disturbance the main line of treatment must be to correct it. Psychological disturbances may exist, but they do not usually require prolonged psychiatric treatment. In the vast majority of cases, however, the main line of treatment will consist in a considerable restriction of the calorie intake. Many diets have been devised for this, but it is often very difficult to ensure that the patient will adhere to them satisfactorily—mainly because of the rigidity or, failing this, the complicated nature of the instructions. For this reason a considerable contribution was made by Marriott when he introduced the diet shown below. This is suitable both for simple obesity and for obese patients with diabetes mellitus who do not require insulin. A patient will generally lose at least 2 lb. per week when on this diet

one at each main meal or all three at one meal as desired ("very small" means *not exceeding 1 oz.*).

4. You may have *nothing else whatever*: particularly note that this means:

No butter, margarine, fat or oil (except for cooking meat, *not fish*).

No sugar, jam, marmalade, honey, sweets, chocolate, cocoa.

No puddings, ices, dried or tinned fruits, nuts.

No bread (except as above), cake, biscuits, toast, patent reducing breads, cereals, oatmeal, "Allbran", "Ryvita", "Vita Wheat".

No barley, rice, macaroni, spaghetti, semolina, sausages, cheese.

No cocktail savouries, alcohol (beer, cider, wines and spirits).

Weigh before you begin, and thereafter weekly, on the *same scales* in the *same clothes*, and at the same time of day.

It may be necessary to help the patient by diminishing the appetite and this can be achieved by giving 5 to 10 mg. of dextroamphetamine sulphate about 30 minutes before each of the main meals of the day. It should not be given too late in the day, however, to those patients in whom it prevents sleep. It must also be emphasised to the patient, who usually wants an easy way to slim, that this drug is no substitute for cutting down the food intake, that it is, in fact, given in order to help the patient to cut down the food intake. *To instil a real desire to lose weight is an absolutely essential beginning to successful treatment.*

Restriction of fluids is sometimes advocated, but there is little point in this. Fluid retention does *not* cause obesity. The main virtue of restricting fluids with meals is that dry food, which cannot be washed down, is not quite so attractive and thus less will probably be eaten. It is quite often observed that an obese person will maintain weight for anything up to 2 weeks even though the calorie intake is considerably less than the energy expended. This is due to fluid retention, and if the patient is followed for long enough it will be found that the retained fluid is always ultimately eliminated.

Results of treatment.—Some obese patients feel lightheaded at times while they are losing weight and most of them feel the cold. At first it requires much effort of will to restrict the food intake, but the ability to do this improves with training. The improvement in general well-being is often quite remarkable and quite enough to illustrate to the patient how important it is to be rid of the excessive weight. When *diabetes mellitus* is present the symptoms usually recede and sometimes even the glucose tolerance test will become normal. Where a patient is hypertensive the blood pressure nearly always falls and symptoms such as headache frequently disappear.

LIPODYSTROPHIA PROGRESSIVA (BARRAQUER—SIMMONS' DISEASE)

Definition.—This is a condition in which there is loss of subcutaneous fat, the loss usually being confined to the upper part of the body.

Etiology.—About 80 per cent. of the reported cases are females. The onset tends to occur in early life, in about half of all cases being before the age of 10 years, and in about three-quarters before the age of 20 years. In the relatively few males who have been reported with the condition, the onset was before the age of 10 years in nearly 90 per cent.

A history of infection preceding the onset has been frequently noted, but in view of the frequency of infections in childhood there seems to be no convincing evidence that these infections were causal.

Two endocrine abnormalities have been noted to occur in a significant proportion of cases, namely, hyperthyroidism and either frank diabetes mellitus or a high blood sugar curve, which is sometimes of the "lag" type. Insulin resistance is sometimes found in those cases which have diabetes mellitus.

Symptoms and Signs—Apart from the psychological disturbances resulting from the abnormal appearance, there are no real symptoms associated with the disease, the patients being in good health, patients in whom there is either associated hyperthyroidism or diabetes mellitus may, of course, have symptoms and signs associated with those conditions.

Characteristically, there is a great loss of subcutaneous fat from the face, neck, upper limbs and trunk, whereas the buttocks and legs may be normal or even have some excess of fat. The loss of fat gives a superficial appearance of emaciation, but closer inspection reveals the muscles to be normal in size and the outlines of the more superficial ones can readily be seen through the skin.

Occasionally cases are seen where the fat has left the lower limbs and is normal on the upper part of the body. It has also been suggested that the relatively common condition in females of obesity of the lower limbs associated with a normal amount of fat on the upper part of the body may be an allied condition.

There is no treatment, the condition, once established, remains more or less stationary, and the expectation of life is unaffected by the lipodystrophy.

stereoisomers of the basic porphyrin nucleus are theoretically possible, but only types I and III are known to occur naturally and only porphyrin III is utilised for hæm synthesis. It is believed that uroporphyrin III is the first recognisable porphyrin produced in the bone marrow. It is decarboxylated to coproporphyrin III and the latter transformed to protoporphyrin and then hæm. Uroporphyrin I, formed as a by-product, may be the precursor of coproporphyrin I which is normally excreted in the urine. The pigment hæmatoporphyrin, which was formerly confused with protoporphyrin, does not occur in nature and the term "hæmatoporphyrinuria" is therefore a misnomer.

Porphyria implies an excess of porphyrins, mainly coproporphyrin, in the urine. It is usually symptomatic of anæmia, liver disease, infectious diseases and various intoxications. Thus in lead poisoning an abnormal amount of coproporphyrin III is excreted, and its estimation in the urine is as sensitive for diagnostic purposes as the finding of punctate basophilia in the blood (see p. 368).

Porphyria is an inborn error of metabolism in which there is abnormal production or failure of utilisation of certain porphyrins and in which large amounts of uroporphyrin appear in the urine. Waldenström (1937) recognises three main varieties, *Porphyria congenita*, *Porphyria cutanea tarda* and *Porphyria acuta*.

1. *Porphyria congenita* is a very rare hereditary disease which manifests itself early in life. Porphyrins, predominantly uroporphyrin I, are found in the bones, the teeth and the urine, which are in consequence red or chocolate brown in colour. There is marked photosensitivity with cicatrization of the skin, loss of digits and hypertrichosis.

2. *Porphyria cutanea tarda* usually appears in early adult life. Photosensitivity recurs intermittently and may be accompanied by abdominal colic and jaundice. During the attacks, porphyrins are diverted from the fæces to the urine, due possibly to episodes of hepatic insufficiency. Many complex porphyrins have been isolated from the urine including uroporphyrins I and III, and in some cases porphobilinogen (see below).

3. *Porphyria acuta* is the commonest and most important of the porphyrias, acute attacks usually occurring in patients between the ages of 20 and 30 years. The disorder is familial and in some cases symptomless, although there is evidence that, in these, attacks may be precipitated by certain drugs such as the barbiturates. Latent, abdominal, nervous, classical and comatose forms have been described. In classical attacks of acute porphyria there is severe burning or colicky abdominal pain, vomiting and constipation with, as the disease progresses, involvement of the nervous system giving rise to paralysis of the limbs and trunk and later of the cranial nerves. Psychological disturbances, tachycardia, hypertension and signs of angiospasm are not unusual. Remissions in the progress of the disease are sometimes dramatic, but the ultimate prognosis is poor, death in respiratory failure being the usual outcome. The urine is reddish brown or purple in colour, either when passed or after standing for some hours. It invariably contains porphobilinogen, which is colourless, but which becomes converted into uroporphyrin III either in the bladder or after the urine has been voided. The finding of porphobilinogen in the urine is specific for acute porphyria and some cases of *porphyria cutanea tarda*. It gives a red Ehrlich's aldehyde reaction but differs from urobilinogen in being inextractable by chloroform.

OTHER DISORDERS OF METABOLISM

The following disorders of metabolism are discussed elsewhere: hæmochromatosis (see p. 680), congenital methæmoglobinæmia (see p. 751), the Fanconi syndrome (see p. 1179), cystinosis (see pp. 1107 and 1179), cystinuria (see p. 1140), alkaptonuric ochronosis (see p. 1105), albinism (see p. 1203), phenylketonuria (see p. 1686), amyloidosis (see p. 1131) and disorders of lipid metabolism (see p. 783).

DONALD HUNTER.

SECTION VI

DEFICIENCY DISEASES

THE VITAMINS

Definition—Vitamins are organic substances, distinct from proteins and carbohydrate, which are present in small quantities in food and which are necessary for the normal nutrition of the body. A substance which by this definition is a vitamin for one species of animal, is not necessarily so for another. For example, ascorbic acid or vitamin C is a vitamin for man and for guinea pigs, but not for dogs or cats.

The vitamins can be divided into those which are water soluble and those which are fat soluble. Since their nature was at first quite unknown, they were labelled with the letters of the alphabet—A, B, C, D, more or less in the order of their discovery. It was soon clear, however, that these were not all pure substances, and with further discovery and labelling in different centres, the nomenclature became chaotic. It is therefore preferable to refer, where possible, to the established chemical name of the vitamin. This is especially important for members of the B complex, but not for the fat soluble vitamins, since here the various members of a given group have a qualitatively similar physiological action.

Vitamin deficiency diseases—If the diet contains less than the requisite minimum of a vitamin for long enough, symptoms and signs develop. Although disease entities are ascribed to various vitamin deficiencies, such pure deficiencies rarely occur except under experimental conditions.

Such dietetic deficiencies are rare in the British Isles where vitamin deficiencies are most commonly associated with conditions interfering with absorption, such as steatorrhœa. Where dietetic deficiencies do exist they are usually associated with some social or psychological abnormality, such as chronic alcoholism or dietary fadism.

THE FAT SOLUBLE VITAMINS

VITAMIN A

This substance is contained in liver (the richest source in the normal diet), butter, cheese, eggs and fish liver oils. It can be formed in the body, however, from the carotenes, and good sources of these are green vegetables, apricots and red palm oil. The international unit of vitamin A is the equivalent of 0.6 micrograms of β carotene. There are two very similar compounds, both having a similar physiological action. One, vitamin A₁, is found in mammals and salt-water fish, whereas the other, vitamin A₂, is found in fresh-water fish.

Vitamin A can be estimated in the plasma, and the curve obtained by frequent plasma estimations after an oral test dose is frequently used as an index of the efficiency of fat absorption. The minimal daily dose required to protect against deficiency has been shown by human experiments to be about 20 I.U. per kg., or 1300 I.U. for an adult man. In order to allow for storage and to supply a safe margin, however, about 2500 to 5000 I.U. per day of vitamin A should be ingested. If the carotenes are the sole dietary source then the intake should be about 7500 to 10,000 I.U.

Vitamin A forms part of the molecule of rhodopsin or visual purple, and hence one of the first signs of deficiency is a high dark adapted rod threshold. This is not

the same as poor night vision, although naturally night vision is inevitably poor when the dark-adapted rod threshold is very high. Psychological factors, however, are very important in determining how well a person can manage in the dark, and may well result in complaints of defective night vision in the absence of vitamin A deficiency.

Other manifestations in man of vitamin A deficiency are xerophthalmia, follicular hyperkeratosis of the skin and keratinising metaplasia, particularly of the respiratory epithelium, the urinary tract and the pancreas. Xerophthalmia is the most serious of these lesions. Keratinisation of the cornea and conjunctiva occurs, and also Bitot's spots, which are thickened, opaque, triangular lesions of the conjunctiva. Infection may supervene to cause a panophthalmitis and resultant total destruction of the eye.

Hyperkeratosis of the hair follicles, particularly on the extensor surface of the limbs, producing the so-called goose skin or phrynoderma also occurs, but it is not absolutely certain that this is entirely due to vitamin A deficiency. It was not produced in experimental vitamin A deficiency when this was studied at Sheffield.

Changes in the respiratory epithelium have been described in children, and it has been suggested that vitamin A deficiency, resulting from malabsorption of fat, may be a factor in producing the lung infections associated with congenital cystic disease of the pancreas.

Vitamin A deficiency resulting from faulty diet, is practically never seen in European communities. It is, however, prevalent in parts of Asia, notably in China and India, and in Africa.

VITAMIN D

Vitamin D is found in large quantities in cod liver oil, and it is present in small quantities in certain foodstuffs such as milk, cheese, butter and eggs.

Furthermore, it is synthesised from various sterols by the action of ultra-violet light, and this reaction occurs both when suitable foodstuffs are irradiated and in the skin when sunlight falls upon it.

When cholesterol is irradiated, a compound called calciferol or vitamin D₂ is obtained, which is active in man but not in chickens. Irradiation of 7-dehydro-cholesterol produces another compound, vitamin D₃, which is effective in man, animals and chicks; this is the compound found in fish-liver oils.

Vitamin D is expressed in International Units, one of which is equivalent to 0.025 micrograms of calciferol. The minimal daily intake is difficult to define, partly because of the variable amount synthesised in the skin and partly because the requirements vary to some extent according to the composition of the rest of the diet; 400 I.U. per day from birth to the age of 20 years is recommended by the Food and Nutrition Board of the National Research Council of the United States of America.

The exact mode of action of vitamin D is not known, but it is necessary for the correct absorption of calcium from the gut and it may also increase the reabsorption of phosphate by the renal tubules. Deficiency results in rickets in the growing child and in osteomalacia in the adult.

As would be expected, deficiency of this vitamin is seen most frequently in countries with relatively small amounts of sunshine. The soot and grime of industrial areas also tend to intensify the situation, since, when these are present, most of the ultra-violet is absorbed from sunshine. This deficiency of sunshine is largely counteracted by children taking vitamin D concentrates, particularly during the winter.

Overdosage with vitamin D can give rise to serious intoxication. Nausea and vomiting, together with muscular weakness are usually the first symptoms. The serum calcium is raised and widespread metastatic calcification occurs, particularly in the blood vessels and in the kidneys, where there may be a serious decrease in function.

VITAMIN E

Vitamin E is found in the germ of cereals, and in green vegetables. There are several compounds which have vitamin E activity. They are all tocopherols, and of these, α -tocopherol is probably the most potent.

Vitamin E acts as an antioxidant, preserving vitamin A and delaying the onset of rancidity in fats. As might be expected, the vitamin is itself rapidly destroyed by rancid fats. There have been no convincing reports of vitamin E deficiency in man, but the tocopherols have been extensively used as therapeutic agents in arterial disease and in muscular dystrophy. Most objective investigations have failed to show any significant effect in these conditions.

VITAMIN K

Vitamin K is present in a large variety of foods and notably in green vegetables. In addition, however, bacteria normally present in the intestine can synthesise the vitamin, and for this reason the daily requirement is unknown.

Two naturally occurring compounds with vitamin K activity are known, K_1 , or 2-methyl-3-phytyl-1, 4-naphthaquinone, and K_2 , or 2-methyl-3-difarneryl-1, 4-naphthaquinone. The former is the compound present in green plants and the latter is produced by bacteria. It has been found that the removal of the side-chains does not result in a loss of vitamin activity, and the simple synthetic compound 2-methyl-1, 4-naphthaquinone (Menadione) is frequently used therapeutically. Many other compounds now are known which possess vitamin K activity, some of them being water soluble.

Vitamin K is necessary for the liver to form prothrombin and deficiency results in a fall in the prothrombin content of the blood. When the level is less than about 15 per cent. of normal, spontaneous hæmorrhage occurs. The first manifestation of this is usually hæmaturia, but spontaneous hæmorrhage, which may prove fatal may occur in any organ in the body.

Bile must be present in the alimentary tract for vitamin K to be absorbed, and deficiency is therefore almost inevitable in any long-standing jaundice of the hepatic or obstructive type. To give the compound by mouth is quite useless under these circumstances, but intramuscular injection is fully effective if liver function is not unduly diminished.

Vitamin K deficiency is also seen in the infant for the first few days after birth. It is presumed that this period occurs after the vitamin K acquired *in utero* is exhausted and before intestinal bacterial synthesis has started. The condition can be prevented by giving the mother about 2 mg. per day of vitamin K during the last week or so of pregnancy.

Steatorrhœa, whether idiopathic or resulting from pancreatic or other disease, also at times associated with vitamin K deficiency, and this can be corrected by giving large doses such as 3 to 5 mg. daily by mouth, though injections may have to be given in severe cases. It is possible that the water soluble compounds may be the most effective when steatorrhœa is present.

The plasma prothrombin level is used as an index of vitamin K nutrition. It is only valid, however, when there is no liver disease (since liver cells produce prothrombin, vitamin K being necessary in the process) and when no drugs of the dicoumarin group have been given. This group of drugs, which are used as anticoagulants in conditions such as coronary occlusion, in some way antagonise the action of vitamin K. Overdosage, resulting in very low prothrombin levels, a spontaneous hæmorrhage, is not rapidly counteracted by vitamin K compounds; the most effective, vitamin K_1 , takes 4 to 12 hours to raise the prothrombin level.

Doses of vitamin K far in excess of the therapeutic amounts do not produce toxic symptoms.

THE WATER SOLUBLE VITAMINS

VITAMIN B₁—ANEURINE OR THIAMINE

Foods rich in aneurine are cereals (where it is mainly found in the germ and the pericarp), legumes, pulses and nuts, pork, ham and bacon, liver, kidney and eggs.

The vitamin has been isolated, identified chemically and synthesised. It is usually measured in milligrammes but 1 international unit is defined as 3 micrograms of aneurine hydrochloride.

Like all vitamins, aneurine was originally estimated biologically, but it is now usual to convert it to thiochrome and to estimate this substance fluorimetrically.

The requirements of aneurine vary with the energy value and carbohydrate content of the diet, but approximately 0.3 mg. per 1000 calories is the minimum intake. Thus, an adult will require something like 1 mg. per day.

Aneurine forms an essential part of two coenzymes which are important in the decarboxylation of the alpha-ketoacids. In aneurine deficiency, pyruvic acid accumulates in the blood and this finding can be used as an estimate of the deficiency, particularly if the production of pyruvic acid in response to a test dose of glucose is measured. It is probably the toxic effects of the accumulating alpha-ketoacids which play a large part in the production of beriberi, the condition resulting from aneurine deficiency. Estimations of aneurine deficiency can also be made by measuring the output of the vitamin in the urine by the thiochrome method.

Deficiency of aneurine gives rise to beriberi (see p. 468), and to pathological changes in the brain which have been described by Wernicke and which are associated with the clinical manifestations of clouded consciousness and ophthalmoplegias of various types.

In western countries deficiency is usually associated with chronic alcoholism where a high carbohydrate intake is associated with a low intake of vitamin B₁. Under these circumstances the manifestations are usually those of peripheral neuritis or of mental changes rather than of wet beriberi.

In the world as a whole aneurine deficiency is most frequently seen among populations whose main cereal is rice. When the pericarp is removed from this cereal, practically no aneurine is left unless the rice has first been partly cooked.

Reactions to large doses of aneurine have occurred which have occasionally been fatal. These have probably been hypersensitivity reactions, however, since they followed injections of the vitamin. Two types of reaction have been described, one resembles anaphylactic shock and occurs after numerous previous injections, and the other presents symptoms somewhat like hyperthyroidism with tremors, palpitation, excitement, giddiness and insomnia.

RIBOFLAVIN

Riboflavin is a bright yellow substance with a yellow-green fluorescence. It is widely distributed in natural foodstuffs but milk, cheese, eggs, liver, green vegetables and yeast are particularly good sources. It is rapidly destroyed when exposed to light, so that considerable loss occurs in substances like milk. Riboflavin is also synthesised by intestinal bacteria, and some of this is absorbed and utilised—a process known as refection, which is common to most of the vitamin B complex. Riboflavin has been isolated and is synthesised on a large scale. It is measured in mg. of pure substance. The quantity present in natural products can be determined biologically by its effect on the growth of rats or chicks, or microbiologically by its stimulating effect on *Lactobacillus casei* (the usual method).

The minimal requirement of riboflavin is about 0.6 to 0.7 mg. per day, but,

since animal experiments indicate that the optimum is about twice this, a daily intake of 1.5 to 1.8 mg for an adult woman and man, has been recommended.

This vitamin forms part of the coenzyme flavin mononucleotide, concerned in the oxidation of carbohydrate, and the coenzyme adenine dinucleotide, which forms part of xanthine oxidase. It is also associated with the retinal pigments.

Riboflavin deficiency in man manifests itself by a dermatitis of seborrhæic type affecting the skin of the nose and round the mouth and of the scrotum or vulva, and by a superficial glossitis which starts with loss of fur in patches from the dorsum and later the tongue is smooth and occasionally fissured and painful, some observers describe the colour as magenta. It is possible that corneal vascularisation and degeneration of the corneal epithelium also occurs. Riboflavin deficiency often occurs in pellagra and signs of the deficiency have been observed to be precipitated when nicotinic acid (qv) has been given. During the War of 1939-1945 neurological abnormalities, particularly optic atrophy with blindness and also deafness, were observed in prisoners of war, and it has been suggested that riboflavin deficiency played a part in these conditions.

None of the signs described above occur specifically as a result of ariboflavinosis. Thus, although the presence of any of them might suggest that the patient is deficient in riboflavin, the proof must lie in recovery when the pure vitamin is given. The excretion of riboflavin in the urine can be measured, but it is not a reliable index of the nutritional state. The riboflavin content of the plasma or of white blood corpuscles can also be measured microbiologically, and these probably are reasonable indices of possible deficiency. In well nourished individuals the mean plasma level is 0.8 µg per 100 ml for free and 3.2 µg per 100 ml for total riboflavin. In white blood corpuscles the mean total riboflavin content is 252 µg per 100 ml.

Manifestations of riboflavin deficiency tend to occur in communities who develop pellagra and where milk is not consumed, it is seen most commonly in Africa, China and India. It is sometimes seen in patients with steatorrhæa, and riboflavin should always be given with aineurin and nicotinamide to patients who have long periods of intravenous glucose as their sole source of nourishment, or who have to receive long courses of wide spectrum antibiotics which prevent the occurrence of refection.

NICOTINAMIDE (VITAMIN B₃)

Nicotinamide and nicotinic acid are equally effective as vitamin B₃, but in bodily issues the vitamin is present practically exclusively as nicotinamide. Moreover, whereas nicotinamide produces no untoward reactions even when taken in large quantities, nicotinic acid in amounts of 25 mg or more causes intense flushing of the skin, and headaches. In vegetable tissues, however, the vitamin is nearly all present as nicotinic acid. The amino acid tryptophane can be converted by the tissues to nicotinamide and thus can also fulfil the role of vitamin B₃. The vitamin is present in cereals, though in maize it is probably present in a bound form, from which it does not become available for human nutrition. The vitamin is also present in good quantities in meat, liver and yeast. It is synthesised by bacterial flora and part of this is available to the body.

The vitamin B₃ content of foodstuffs is usually estimated by a chick-growth method, but for samples of biological fluids it is more usual to measure the growth stimulation of *Lactobacillus arabinosus*.

The requirements of nicotinamide are not easy to estimate, partly because of the role of tryptophane, partly because of the process of refection and partly because of the occurrence of the vitamin in forms unavailable to the body. It is probable that 10 to 20 mg per day should be entirely adequate.

Nicotinamide forms part of Coenzyme I and Coenzyme II, which are dehydro-

genases and are concerned in a variety of metabolic reactions such as the conversion of lactate to pyruvate and glutamic acid to α -ketoglutaric acid.

Nicotinamide is excreted in the urine partly as N^1 -methyl nicotinamide, a substance which has a blue fluorescence. This substance can readily be measured and it falls to very low levels in patients suffering from nicotinamide deficiency.

Deficiency of vitamin B_3 is the major factor in the production of pellagra. It seems to be most common in maize-eating communities. In European communities, apart from the poor of maize-eating areas, it is seen mostly in conjunction with chronic alcoholism in steatorrhœa and in mental hospitals. Deficiency can also occur after prolonged treatment with wide spectrum antibiotics.

PYRIDOXINE (VITAMIN B_6)

Three compounds occurring in foodstuffs have vitamin B_6 activity, pyridoxine, pyridoxal and pyridoxamine. Although the last two compounds are the ones found in the tissues as part of decarboxylating and transaminating enzymes, the first is the more effective when given by mouth. This is probably because it is not so readily utilised by intestinal organisms as the others, so that a greater proportion is absorbed. Pyridoxine is also concerned in the oxidation of unsaturated fatty acids and seems to be necessary for normal adrenal cortical function. Further, it appears to be necessary for the normal metabolism of tryptophan and when supplies are deficient, an abnormal tryptophan derivative, xanthurenic acid, appears in the urine. This forms the basis of suggested tests for vitamin B_6 deficiency. Vitamin B_6 is widely distributed in foodstuffs, the richest sources being yeast, wheat germ, liver, pulses and cereals. The exact daily requirement is not known, but on the basis of animal experiments it is probably about 1.5 mg. per day.

Experiments on man have shown that B_6 is essential for human nutrition. The symptoms which arise are many and varied; mental depressions and confusion, seborrhœic skin lesions round the nose, eyes and mouth, cheilosis and glossitis, albuminuria, hypochromic anæmia and granulopenia have all been induced by deficiency and have been subsequently cured by giving pyridoxine. Some cases of pellagra appear to require pyridoxine in addition to nicotinamide and riboflavin.

There are several compounds similar to pyridoxine, which antagonise its action and act as anti-vitamin B_6 substances. The most potent of these is desoxy-pyridoxine. The substance is useful experimentally, but so far does not seem to have therapeutic applications.

PANTOTHENIC ACID

Pantothenic acid is very widely distributed and this may account for the fact that certain evidence of deficiency in man has not yet been produced. It forms part of the prosthetic group of coenzyme A, an important enzyme concerned in acetylation. It seems also to be concerned with the function of the adrenal cortex, since animals deficient in the substance show evidence of cortical deficiency together with definite histological lesions in the adrenal cortex. Also pantothenic acid-deficient pregnant rats give rise to young with absence of eyes and abnormalities of the central nervous system. It has been suggested that deficiency of this nutrient was responsible for a syndrome characterised by a subjective feeling of burning in the feet and legs and seen in prisoners of war in the Far East in the War of 1939-1945.

Biotin.—This substance is excreted in the faeces and urine in greater quantities than it is ingested; it is probably synthesised in very adequate quantities by intestinal organisms. Avidin, a protein in egg-white, combines with biotin and renders it unavailable. In man deficiency of biotin has been produced by feeding large quantities of egg-white and the chief manifestations were a scaly dermatitis, anæmia and muscle pains.

It is very unlikely that spontaneous biotin deficiency occurs in man

Choline—Choline is probably necessary in human nutrition in amounts of about 500 mg per day. The requirement, however, is almost certainly related to the intake of other substances such as methionine. Animals deficient in choline develop fatty livers and hæmorrhagic lesions in the kidney.

Choline is one source of labile methyl groups, it is also concerned as a lipotropic factor in preventing the undue deposition of fat in the liver, it is concerned in the formation of phospholipids and it is necessary for the formation of acetylcholine.

Choline is frequently used in the therapy of liver disease, but it seems possible that a large part of choline given by mouth is broken down in the intestine to trimethylamine, so that it is more likely to be effective when given parenterally than by mouth.

Inositol—The function of inositol in nutrition is not known and there is no evidence to suggest that deficiency of this substance occurs in man.

Para aminobenzoic acid—There is no evidence for man that this substance must be present in the diet, it is part of the molecule of folic acid. It is necessary for the metabolism of many pathogenic organisms and metabolic pathways involving this substance are blocked when sulphonamides are present in sufficient quantities. The molecules are very similar and this was the first known example of the antimetabolic action of compounds structurally related to substances occupying key places in metabolic processes.

Folic acid and citrovorum factor or folinic acid—Folic acid (pteroylglutamic acid) occurs widely in foodstuffs, mostly in the form of the conjugates, pteroyltriglutamic acid and pteroylheptaglutamic acid. It is converted in the body in the presence of vitamin C to folinic acid (citrovorum factor) which is active and which is itself effective when given in appropriate cases of anaemia. Folic acid is also synthesised by the intestinal flora and this probably forms an important part of the total intake.

Megaloblastic anaemias of various types respond to folic acid. This includes true pernicious anaemia, but here such treatment is dangerous, since subacute combined degeneration of the cord may be precipitated, it seems probable that what little vitamin B₁₂ (q.v.) there may be available is utilised for hæmopoiesis when folic acid is given, thus precipitating evidence of B₁₂ deficiency in the central nervous system. Some cases of macrocytic anaemia, usually associated with steatorrhœa or pregnancy, do not respond to vitamin B₁₂ but are responsive to folic acid or citrovorum factor. When folic acid is given to patients with steatorrhœa the megaloblastic anaemia usually responds, the stools become less watery and the glossitis may heal.

VITAMIN B₁₂ (CYANOCOBALAMIN)

This vitamin, which contains cobalt, and which exists as three closely related compounds is Castle's extrinsic factor. Deficiency leads to megaloblastic anaemia, to superficial glossitis, to the neurological lesions of subacute combined degeneration of the spinal cord and to a general lack of well-being. Such deficiency does not occur in man as a result of deficient intake, but usually secondary to degenerative changes in the stomach resulting in an absence of Castle's intrinsic factor. It seems that this substance may either protect B₁₂ from destruction in the alimentary tract or aid in its absorption, because the vitamin is ineffective by mouth unless accompanied by sources of intrinsic factor or unless it is given in doses about one hundred times greater than is necessary parenterally.

Single parenteral doses of the order of 5 to 10 µg will cause a considerable response in cases of pernicious anaemia, but for maintenance the requirement is about 4 µg per day, administered parenterally twice a month.

Vitamin B₁₂ has also been found to stimulate the growth of children and of animals, it is certainly closely related to animal protein factor. Very large doses (1000 µg

per day) have been claimed to relieve the pain of trigeminal neuralgia and of herpes zoster. It is also possibly concerned in preventing some of the complications of diabetes mellitus.

VITAMIN C

Vitamin C or l-ascorbic acid is widely distributed, green vegetables, citrus fruits and potatoes, being particularly good sources of the substance. It is, however, easily destroyed in cooking, because it is rapidly oxidised when heated in air, and because in many foodstuffs in which it occurs, ascorbic acid oxidase is also present. This rapidly destroys the vitamin whilst the foodstuff is being warmed up in the initial stages of cooking. In general, vegetables cooked for large numbers of people contain very small amounts of ascorbic acid, whereas home-prepared vegetables are much more satisfactory. This is because it is not easy, on a large scale, to raise the temperature of vegetables rapidly to boiling point and so destroy the ascorbic acid oxidase before it has oxidised much of the ascorbic acid. In the home, vegetables can be "blanched" in boiling water, and this rapidly destroys the ascorbic acid oxidase.

Ascorbic acid can readily be estimated chemically, since it will reduce methylene blue or the dye, 2, 6-dichlorophenolindophenol.

The requirements of ascorbic acid are not exactly known, but human experiments have shown that a daily dose of 10 mg. will cure clinical scurvy and is sufficient to prevent the onset of scurvy at least for over a year. Ascorbic acid is utilised, however, more rapidly than usual during stress and when infections are present, so that the League of Nations Technical Commission's recommendation of 30 mg. per day is probably about right. The National Research Council (U.S.A.) recommends 75 mg. per day, and this would seem to allow a considerable margin of safety.

In spite of the ease with which ascorbic acid can be estimated and of the fact that its position in tissues can be demonstrated by histochemical methods, little detail is known of the actual action of the substance. It is concerned in tyrosine metabolism and it seems to be essential for the production of collagen; it is necessary for the conversion of folic to folinic acid. It is also present in very large quantities in the adrenal cortex and depletion occurs when corticotrophin (A.C.T.H.) is given.

Ascorbic acid deficiency can be estimated by a saturation test devised by Harris, in which the vitamin is given in a dose of 5 mg. per 1 lb. body weight each morning. The ascorbic acid content of the urine secreted between 4 and 7 hours after the test dose is estimated each day, and this shows a sharp rise after the procedure has been repeated a sufficient number of days to saturate the subject. Normally only 1 or 2 days are required for saturation.

Deficiency can also be estimated by a determination of the ascorbic acid content of leucocytes and platelets. A concentration below 2 mg. per 100 g. indicates severe depletion. Estimation of the ascorbic acid concentration in plasma is not so useful.

SCURVY

Scurvy is a disease characterised by subcutaneous ecchymoses, ulceration and hæmorrhage of the gums, anæmia, debility and failure of wounds to heal.

Ætiology.—Until about 150 years ago scurvy was the scourge of sea voyages and was a factor of paramount importance in naval warfare. Owing to this disease, sea-going fleets had to be relieved every 10 weeks so that the men could be rehabilitated ashore. It was asserted that, when Lind's recommendation of a daily ration of 1 oz. of lemon juice was implemented, it was equivalent to doubling the fighting strength of the British Navy. A further example of the effects of the disease on sea

voyages is furnished by Anson's journey round the world; during 3 months of the voyage more than half the men on two of the ships died from scurvy.

Scurvy also was seen until comparatively recently in infants fed on dried milk powders (see Infantile Scurvy) but, owing to prophylactic measures, this, too, is rarely seen among European communities.

At the present time in western society, scurvy is most usually seen among old people (particularly men) of meagre means, who are living by themselves—so-called "Bachelor's Scurvy". In them it appears because of a deficient intake of foods containing vitamin C and tends to occur in the late spring.

Pathology.—It is generally agreed that the fundamental defect in scurvy is a failure to deposit adequate amounts of intercellular material, of collagen, osteoid material or of dentine. Hæmorrhages occur into the skin, subcutaneous tissues, under the periosteum and into the joints, pleura and pericardium. Furthermore, bones are not adequately calcified, the structure of growing bone is disorganised and wounds do not heal properly. Ascorbic acid is also necessary for the proper maturation of erythrocytes and anæmia of variable type also occurs in scurvy.

Symptoms and Signs.—Scurvy usually has an insidious onset and it is difficult in patients who present all features to assess the earliest manifestations. However, in experiments on human volunteers who had been saturated with the vitamin it was noted that after some 17 to 20 weeks of ascorbic acid deprivation hyperkeratosis of the hair follicles began to appear. This was usually first seen on the outer aspect of the upper arms and was also seen on the back, buttocks, backs of the thighs, calves and shins. Affected follicles became plugged with keratinous material and the hair became coiled up inside. Following this, the capillaries round the follicle became dilated and filled with blood and, finally, hæmorrhage occurred. After about 30 weeks, hæmorrhages occurred in the tips of the interdental papillæ of the gums and later swelling and more gross degrees of hæmorrhage appeared. Bacterial examination of the gums of patients with scurvy reveals that they are infected with large numbers of Vincent's spirochaetes and anaerobic fusiform organisms. Also, after about 30 weeks, scars which had been made before deprivation of ascorbic acid became livid and red, and at about this time freshly made wounds failed to heal properly. Subcutaneous ecchymoses also occurred at about this time in one subject, but in the experimental disease large subcutaneous ecchymoses did not appear to feature so prominently as they do in the spontaneously occurring condition. Two experimental subjects experienced sudden cardiac pain, electrocardiographic changes being found. It seems probable that these symptoms might have resulted from hæmorrhage into the heart muscle and a similar occurrence or hæmorrhage into the pericardium might well account for the sudden deaths which were a feature of florid scurvy before measures of preventing and curing the disease were known. During the experiments carried out at Sheffield, it was also noted that subjects, who already had acne before ascorbic acid deprivation, experienced an exacerbation of this condition at a time when manifestations of scurvy were developing.

Although anæmia is a feature of naturally occurring scurvy it did not occur in the experimental subjects. This may well underline the fact that under natural conditions man rarely suffers from deficiency of one nutrient, and scurvy, as seen in clinical practice, is almost certainly associated with deficiencies of other nutrients as well as of ascorbic acid.

Diagnosis.—The concurrence of subcutaneous ecchymoses, hyperkeratosis of the hair follicles with perifollicular hæmorrhages, and swollen hæmorrhagic gums, should suggest the diagnosis at once, and a total and differential white blood count should exclude leukaemia, a condition which can resemble scurvy very closely. In mild cases, however, where the skin lesions are the only clinical manifestation, it is not possible to make a diagnosis without laboratory aids, the lesions themselves not being pathognomonic of scurvy. Either the saturation test or the level of ascorbic acid in the

white cell and platelet layer (see Vitamin C) should help to establish the diagnosis. The diagnosis can also be established by the response to ascorbic acid, since healing and retrogression of the lesions occur rapidly when adequate treatment is given.

Prognosis.—Untreated, and with a continuation of a scorbutic diet, death will occur. With all but the most serious cases in which sudden death can occur, however, the response to treatment is entirely satisfactory.

Treatment.—**PROPHYLAXIS.**—The diet should contain at least 10 mg. of ascorbic acid per day and preferably more than 30 mg. (see Vitamin C).

The established disease is best treated (a) by giving 1000 mg. of ascorbic acid daily for 5 to 10 days followed by a daily intake of 30 mg. or more, (b) by accompanying this by a good nutritious diet of high vitamin content (since other nutrients than vitamin C will almost certainly have been in poor supply).

It should be noted that healing occurred in subjects with experimentally produced scurvy when they were given as little as 10 mg. of ascorbic acid per day. It would seem, however, that, since it is quite harmless to give saturating doses of ascorbic acid, it would be better to do this and thus ensure that a maximum therapeutic effect is obtained.

GEORGE A. SMART.

INFANTILE SCURVY

Infantile scurvy—known on the Continent as Barlow's disease—is identical in its pathology with the adult form of the disease, its special clinical features being due to the anatomical and physiological peculiarities of early life.

Ætiology.—The disease usually appears between the eighth and twelfth months—both sexes being equally affected. As in adult scurvy, the essential cause is the absence from the dietary of a sufficiency of anti-scorbutic vitamin. Any heating of milk reduces the amount of vitamin C present. Certain commercial processes in condensing or drying milk may completely destroy the vitamin. Pasteurisation is the least harmful process. In any case the addition of vitamin C to the diet is so easy that it is better to make milk a safe food by some heating process rather than to rely on it as a source of anti-scorbutic vitamin. A few cases have been recorded in which the child had been fed on the breast only; it is probable that in these the mother's diet had been deficient in fresh constituents. The normal *prophylactic* dose of vitamin C for the infant is about 25 mg. daily.

Pathology.—The chief changes are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hyper-vascular, thickened and separated from the subjacent bone by a layer of partially organised blood clot. There is no sign of inflammation, and no hard bone is formed in the periosteum, except in very long-standing cases; in which circumstances the muscles surrounding the bone may be infiltrated with blood or serum, and look sodden. The bone exhibits rarefaction, and may be fractured. There may be hæmorrhagic effusions into the joints or serous cavities. The organs exhibit no characteristic change.

Symptoms.—The onset is gradual, the first symptoms noticed being often a refusal of food, along with fretfulness and restlessness. There is a tendency for the child to resent being handled. Meanwhile the general nutrition is usually unimpaired, and the child's colour is often fresh and healthy looking. After a variable period the more prominent symptoms appear. The most striking of these is extreme tenderness of the legs, which causes the child to scream loudly when touched or even when approached. In a well-marked case some swelling will be found, usually of the lower end of the femur or upper end of the tibia. Involvement of the arm bones is much rarer. The skin over the swelling is often tense and glossy, and may be slightly œdematous; but there is no local heat. Soft crepitus may be elicited on handling the

and a change from any overheated milk or milk product to plain milk just brought to the boil for safety. In very severe cases ascorbic acid can be given intravenously. Iron is useful if there is anæmia present.

Scorbutic infants should be handled carefully, and the clothing so made that it can be easily taken off and on. If it is necessary to move the child about it should be carried on a pillow. The affected limb should be supported by light splints or wrapped in wet towels, which, if allowed to dry in position, afford considerable support. In mild cases a covering of cotton-wool secured by a light bandage is sufficient protection.

RICKETS

Definition.—Rickets is a disease of nutrition occurring in early childhood. It mainly affects the growth of the bones, but may be accompanied by tetany in some cases. Associated nutritional disorders produce anæmia and a tendency to catarrh of the mucous membranes in many instances.

Ætiology.—Various theories have been held in the past as to the cause of rickets, but it is now clear that it is essentially due to absence of vitamin D in sufficient amounts to promote adequate calcification of growing bones. The fault is usually dietetic and not only because of deficiency of vitamin D-containing foods but also because excess of carbohydrate promotes more rapid growth than calcification can cope with. The ultra-violet rays of sunshine can manufacture vitamin D in the skin. Hence all those conditions which prevent the free access of unfiltered sunshine to the skin of the growing infant may be regarded as predisposing to rickets.

Pathology.—The chief changes are in the bones. Section through the end of a long bone shows that ossification, instead of proceeding in an orderly way, is greatly disorganised. In the zone of proliferation of the cartilage the cells show excessive multiplication, and are arranged irregularly instead of in columns. A broad bluish area results, which is the cause of the thickening of the epiphysis. In addition to this, calcification between the cells is defective, the affected area shows excessive vascularity, and the new bone formed is soft and deficient in lime. The whole process has been summed up in the statement that "there is an excessive preparation for ossification and a defective accomplishment of it". In addition, the vascular layer of the periosteum is thickened and the marrow congested.

Chemical analysis shows that the bones contain only from 30 per cent. to 50 per cent. of calcium, instead of the normal 60 per cent. or more. They may show signs of old or recent fracture. Other organs show no characteristic change.

Symptoms.—The disease can rarely be recognised before the sixth month. Amongst the earliest indications to attract attention are restlessness and irritability, sweating about the head, especially when asleep, and a tendency on the part of the child to kick off the bedclothes at night. There is no wasting, indeed the infant may be abnormally fat, though usually flabby and pale. The appetite is capricious. An early sign, found sometimes as early as 3 months, is *cranio-tabes*: this is a curious softening of the bones of the occipital region.

As the disease progresses, it will be found that dentition is delayed, and that changes in the bones become manifest. They first show themselves in the epiphyses of the ribs, which enlarge and form a row of knobs down the sides of the chest (the rickety rosary). Enlargement of the epiphyses of the bones of the limbs then takes place, being most conspicuous at the lower end of the radius.

The softening of the bones leads to various deformities. The chest sinks in at the line of junction of the ribs and cartilages, so that a broad groove forms, running downwards and outwards towards the axilla (Harrison's sulcus). The bones of the limbs bend, the femur curving forwards and outwards, and the tibia bending sharply forwards and often also outwards at its lower third; there may also be a curving of

the upper part, leading to "bow-leg". The humerus and bones of the forearm may become bent in an outward direction, as the child sits supporting itself on the hands, and the clavicle may show a sharp kink at the junction of the inner and middle third. The pelvis becomes flattened. Greenstick fractures of the limb bones are not uncommon.

The skull shows striking changes. It is usually somewhat enlarged, elongated and flattened on the vertex (box head), the anterior fontanelle remaining widely open long after the normal period of closure at the eighteenth month. There may be pronounced thickening of the frontal and parietal eminences, leading to the so-called "hot-cross bun" or bossed head, especially in cases complicated by anæmia with enlarged spleen.

The muscles are often so weak and flabby that paralysis is simulated, and the ligaments may be so lax that the limbs can be bent into almost any position ("acrobatic rickets"). In consequence also of the laxity of ligaments, kyphosis often develops in the lower lumbar region (rickety spine).

The blood usually shows a varying degree of anæmia of the hypochromic type, and in a few cases the changes are so profound as to resemble those met with in chlorosis. Biochemical studies show a raised blood phosphatase, a lowered blood phosphorus and in severe cases a lowered blood calcium.

The digestive system is usually deranged. Chronic diarrhoea with pale, offensive stools is not uncommon. The abdomen is distended so that the child has a pot-bellied appearance. In the production of the distension, muscular weakness, intestinal fermentation and the pushing down of the diaphragm by the sinking in of the chest all play a part. The edge of the liver can often be felt at a lower level than normal, partly from displacement and in part from enlargement through fatty change. The spleen is also palpable in a considerable number of cases, although this is due more to its being pushed down than to actual enlargement.

In the respiratory system bronchial catarrh is very often present, and not uncommonly results in broncho-pneumonia. In the nervous system the disease shows itself by general nervousness and irritability, and in some cases by the development of laryngismus stridulus, tetany or even convulsions, of all of which rickets is a strong predisposing cause.

The clinical picture here outlined refers to fully developed rickets, which has become a rare disease in Britain. Radiographic examination confirms the clinical findings in the established case, but also it reveals changes in the growing ends of the long bones at a stage when clinical examination is essentially negative. This mild type of rickets is relatively common, and indeed some observers regard it as almost "physiological" in the sense that for calcification to be optimum in the rapidly growing bones of the small child a high degree of "saturation" with vitamin D and calcium seems to be necessary. Radiographic studies have also drawn attention to the fact that the clinical diagnosis of rickets based upon enlarged epiphyses and bow-legs, for example,

when the child is held up by the armpits. In severe cases this may not happen, and a radiograph may be required to settle the diagnosis. Bowing of the legs in the toddler is often more due to muscular development than to bent bones. If the muscular weakness is pronounced infantile paralysis may be imitated, but the history, the retention of the reflexes and the presence of other signs of rickets should prevent mistakes.

Prognosis—Rickets is not fatal *per se*, and usually passes off spontaneously after the second year, although the deformities of the bone may persist for a long time. Even these, however, have a wonderful way of righting themselves without any special treatment. On the other hand, rickets is a very serious complication of other diseases, especially of broncho pneumonia and diarrhoea, and adds greatly to their fatality if present.

Treatment—Rickets can be prevented if the child is properly fed and cared for. Breast feeding for the first 9 months is the best safeguard, provided that the mother's diet is satisfactory, but it must always be remembered that the disease is apt to develop in children who are kept *too long* on the breast. The increasing use of dried milk fortified with vitamin D is undoubtedly an important factor in the decrease of rickets to its serious forms. After weaning, the premature and excessive use of starchy foods must be avoided. Care should be taken that the diet contains an adequate amount of animal fat. Plenty of fresh air, sunlight and exercise are also important factors in prophylaxis. It is probable that all infants in temperate and cold climates require a daily supplement of cod liver oil or the official "cod liver oil compound" to give 800 international units of vitamin D daily for the first 2 years of life. The same dose should be used throughout to give a relatively larger amount to the small infant.

If the disease has already developed, the diet should be altered in accordance with the requirements indicated above, the most important point usually being to increase the allowance of cow's milk, which should not fall below $1\frac{1}{2}$ pints per diem during the second year of life. Cod-liver oil and halibut oil (or one of the artificial substitutes containing vitamin D) are most useful, having a specific influence on the disease, but iron may also be given with advantage if there is anaemia. It is wise to start with a pure vitamin D concentrate in adequate dosage for about a month to bring the disease under control. Sun baths or exposure to the rays of the mercury-vapour lamp have a definitely curative effect but act more slowly than vitamin D concentrates.

To prevent bending of the legs, long splints may be applied, projecting beyond the feet, so as to make standing impossible. Orthopaedic treatment may be required for the more permanent deformities. Alimentary and respiratory complications should be treated by the measures appropriate to them.

LATE OR ADOLESCENT RICKETS

After growth has ceased certain deficiency and metabolic disorders may produce osteomalacia. Between this adult manifestation and the usual infantile type of rickets there is a series of rare and rather bewildering conditions in young and older children in which the radiogram changes at the ends of the still growing bones resemble those of rickets. In some cases the cause is found in a missed case of coeliac disease where failure of fat absorption means also failure of vitamin D and calcium absorption. Another group, termed *renal rickets*, is found when a child, say of school age, has knock-knee, some stunting of growth and albuminuria. Investigation of the renal system may reveal other signs of a chronic nephritis and at post-mortem examination small contracted kidneys may be found. The blood usually shows a high blood urea and raised blood phosphates. Modern biochemical investigations indicate that the term renal rickets may cover various disorders, in some of which the renal tubules

are allowing the loss of amino acids or of calcium or of other metabolites leading to metabolic disorders such as a chronic state of acidosis with reduced plasma bicarbonate and increased chlorides. The "Fanconi syndrome" is the name given to one variant with amino aciduria, glycosuria and acidosis. In Lignac's disease cystine storage occurs and bone changes have been noted. Some of these conditions have been described as vitamin resistant rickets. It still seems possible that certain rare cases of what appears to be an ordinary deficiency rickets with no other metabolic disorders require very large doses of vitamin D to prevent or cure the condition. This is a genuine vitamin-resistant rickets and may be familial. Treatment of the various metabolic disorders mentioned is unsatisfactory. Usually it is advisable to give alkali in the form of citrates and citric acid. Orthopaedic help may be needed to deal with the bony deformities.

"Fetal" and "congenital" rickets are ambiguous terms which have been loosely used to cover several distinct pathological conditions, amongst which are achondroplasia, mollities ossium and osteogenesis imperfecta. They are best avoided. So called "scurvy rickets" and "acute rickets" are identical with infantile scurvy although rickets often co exists with the latter, seeing that both are due to faulty feeding.

ALAN MONCRIEFF

BERIBERI

Synonyms—Polyneuritis Endemica, Hydrops Asthmaticus, Kakke, Barbier

Definition.—A nutritional disease due to deficiency in vitamin B₁, and occurring most frequently in tropical regions where polished rice constitutes the main article of dietary. It is characterised typically by congestive heart failure and oedema (wet beriberi), and, or, multiple symmetrical polyneuritis especially involving the lower limbs progressing to atrophic paralysis, sensory loss and ataxic gait (dry beriberi). The acute and subacute forms with congestive heart failure respond well to crystalline vitamin B₁ when given parenterally in adequate amounts early in the disease. Treatment of the chronic "dry" beriberi is less satisfactory.

Ætiology.—The rice-eating populations of India, Japan, Malaya, the Dutch East Indies and Philippine Islands are mainly affected, but the disease is also endemic in Newfoundland and Labrador, where the population eat chiefly white wheaten flour. Though the disease is specially rife amongst people eating polished rice, rice *per se* is not essential, any dietary deficient in the antineuritic vitamin B₁ being a potential source of danger. Parboiled and undermilled or husked rice are not deficient in vitamin B₁. During milling the husk, pericarp and germ, which are rich in protein, fat, phosphorus and vitamin B₁ (see p. 457) are removed, leaving the white polished rice poor in these constituents. Milled rice, white flour, breakfast cereals, macaroni, spaghetti and cane sugar contain practically no vitamin B₁. This vitamin, known also as "aneurine hydrochloride" or "thiamine hydrochloride" was synthesised in 1937 in crystalline form (1 mg. = 333 international units), and is available for therapeutic purposes. It is mainly found in yeast, Marmite, whole seeds, the germ of cereals, pulses and nuts. Aneurine is a precursor of cocarboxylase, which removes pyruvic acid—from the tissues and blood. Excess of pyruvate can be demonstrated in the blood in beriberi, the value rising from a normal of 0.4–0.6 mg. to 1–7 mg. per 100 ml. The quantity normally present in the cerebrospinal fluid is also increased. When no complicating factor is present, 5 mg. of vitamin B₁ will restore the blood to a normal value in 10 to 15 hours. B₁ is readily absorbed and is stored in the liver, kidneys and heart, but the storage capacity is limited and clinical exper-

ence indicates that symptoms may appear in man in a few weeks with a B_1 deficient diet.

Pathology.—In "wet beriberi" there is an acute congestion of the mucosa of the duodenum and lower end of the stomach, sometimes associated with pin-point hemorrhages. The peripheral nerves show a Wallerian degeneration, with possibly an axonal degeneration of the neuron involved. The sheath of Schwann may exhibit multiplication of its nuclei and invasion by leucocytes. The vagi, phrenic nerves and sympathetic system may present stigmata of degeneration, and sometimes the anterior horn cells of the spinal cord and the nuclear connections of the vagus in the floor of the fourth ventricle are said to be implicated. Scattered foci of degeneration also may occur in the posterior columns of the spinal cord. The cardiac muscle may show degenerative changes, while the naked eye appearances are those of fatty degeneration associated with dilatation and hypertrophy, especially involving the right side. Nutmeg-liver, œdema of the soft tissues and effusions into the serous cavities are common. Wenckebach regarded œdema of the heart muscle with resulting loss of contractility, and not involvement of the vagi, as responsible for the cardiac condition. Weiss and Wilkins point out that the myocardium shows an unaltered water content, with "hydropic" degeneration of the muscle and conductive fibres, and increase in intercellular substances. In acute beriberi the essential condition appears to be an acute metabolic breakdown affecting both the cardiac and nervous system which responds therapeutically to vitamin B_1 . In experimental animals the process underlying the nervous manifestations is a dysfunction associated with degenerative non-inflammatory changes. It has been suggested that the term "neuropathy" is more accurate than "polyneuritis". In long-term deficiencies, however, damage to tissue may ensue which cannot be repaired merely by correcting the vitamin deficiency. Cases of so-called "dry" beriberi rarely come to necropsy unless suffering from intercurrent disease.

Symptoms.—There is generally a latent period of some 2 to 3 months before deficiency symptoms become manifest. Typically the onset is gradual, being characterised in the initial stages by epigastric discomfort, nausea and perhaps vomiting and diarrhœa. Later, polyneuritis, with palpitation, shortness of breath and weakness develop, the subsequent clinical picture varying according to involvement of the peripheral nerves, the vagus or the sympathetics. The disease runs an afebrile course, except possibly in its early stages. Recurrences are common. Several different types are described:

(1) **LARVAL OR AMBULATORY CASES.**—There is numbness of the legs with patchy anaesthesia and diminution of knee-jerks, all of which quickly disappear if the condition is recognised and a more varied diet containing vitamin B_1 be given.

(2) **ACUTE FULMINATING BERIBERI.**—The onset is sudden, often with anorexia, epigastric discomfort, nausea and perhaps vomiting, while paræsthesia and loss of sensation especially over the front of the legs and dorsum of the feet are common. Congestive heart failure rapidly follows (see p. 903), and, or, widespread paralysis of the limbs and trunk. Alteration of the voice or aphonia due to laryngeal paresis, diaphragmatic paralysis secondary to phrenic nerve involvement, bilateral facial paralysis and paralysis of the muscles of mastication may supervene. Death may follow in a few hours to a few days. Acute cardiac failure may also suddenly develop

involvement. There are manifestations of dilatation of the heart, especially the right side (see p. 810). Several factors may contribute to the œdema, (1) intracellular œdema associated with failure of cell nutrition; (2) cardiac failure, (3) decreased plasma proteins and (4) secondary renal insufficiency. When the nervous manifestations are slight and the patient can still do muscular work, œdema is more likely to develop. Sudden death may occur without clinical evidence of cardiac involvement.

(4) **CHRONIC BERIBERI (Dry form)**—This is similar to the above except that œdema is absent and the disease runs a more chronic course. The onset is insidious, gastro intestinal disturbances may be absent, the dominant features being wasting and weakness of the muscles, associated perhaps with cardiac irritability. Numbness of the limbs or face, cramps in the calf muscles and coldness of the feet may be troublesome. In rising from the squatting position the patient levers himself up by placing his hands successively on his knees and thighs. Foot drop, high-steppage gait, muscular tenderness and anæsthesia, sometimes of glove and stocking distribution, are frequently present. Generally leg symptoms are advanced before the arms are seriously affected but wrist drop and the high steppage gait may co-exist. Clinically, the disease closely resembles alcoholic neuritis and the neuritis in pellagra, both of which are now regarded as being due to a deficiency in B_1 . Wet beriberi may develop at any time, but this is less likely if the neuropathy is sufficiently severe to keep the patient resting. Lesions of the cranial nerves other than the vagi are very rare.

(5) **INFANTILE BERIBERI**—This disease occurs especially in the Philippine Islands and Japan, where it is responsible for many deaths in breast fed infants whose mothers are afflicted with latent or clinical beriberi. More than 50 per cent of cases show symptoms between the third and fourth weeks of life. The disease occurs in both acute and chronic forms. In the latter gastro intestinal features like anorexia, vomiting, diarrhoea or constipation occur, associated with wasting, pallor, œdema, mainly involving the face and extremities, dyspnoea and other evidences of cardiac insufficiency. Aphonia or an altered cry is often striking, and loss of knee jerks is present in 75 per cent of cases. In the acute form death may occur with great rapidity, the infant developing convulsive attacks, suffering severe colicky pain and presenting cyanosis, dyspnoea and muscular rigidity.

(6) **SECONDARY BERIBERI** may be associated with (1) gastro intestinal diseases leading to defective absorption of vitamin B_1 , (2) chronic alcoholism or (3) pregnancy, diabetes, febrile states or diseases increasing metabolism which lead to a relative deficiency by increasing the demand for B_1 .

(7) **ASSOCIATED DEFICIENCY DISEASES**—Visual disturbances are probably very rare in uncomplicated beriberi, but in prisoners of war nutritional polyneuritis was frequently associated with failing vision, photophobia and pallor of the temporal halves of the optic discs. Though undoubtedly nutritional in origin, there is no satisfactory evidence that retrobulbar neuritis or optic atrophy is due to deficiency in B_1 . It is seen apart from beriberi in lactating women in Japan, and in advanced cases there is not infrequently deafness and ataxia as well. This fully developed syndrome was not uncommon in prisoners of war in the Far East associated with beriberi. Other deficiency conditions which may occur in beriberi patients include scrofula dermatitis (ariboflavinosis), night blindness (vitamin A deficiency), skin and mucous membrane lesions due to nicotinic acid deficiency (pellagrous beriberi), and scurvy due to lack of vitamin C (ship's beriberi).

Diagnosis—Wet beriberi has to be diagnosed from cardiac failure, nephritis, famine œdema and severe ankylostomiasis, while the dry form has to be differentiated from other causes of peripheral neuritis post-diphtheritic paralysis, tabes dorsalis and progressive muscular atrophy. The dietetic history is important and multiple cases of neuritis, especially if associated with œdema, should always suggest beriberi. So

should oliguria and œdema in a breast-fed baby. Vitamin B₁ is greatly decreased or practically absent from the urine in cases of beriberi, and this test (p. 457) may determine the diagnosis in doubtful cases. Volhard's diuresis test may also be helpful, since there is water retention in beriberi.

Prognosis.—In acute beriberi with cardiac involvement, whether in adults or infants, the prognosis largely depends on the administration of large doses of crystalline vitamin B₁ parenterally; this improves the cardio-vascular condition in "wet" beriberi, and is often a life-saving measure in acute fulminating beriberi with cardiac failure, provided it be given intravenously or intramuscularly in adequate dosage. If the patient survives the first 2 weeks and an adequate maintenance dosage of B₁ be continued, recovery ensues. In infants the disease tends to run a rapid course and shows a high mortality unless promptly treated. Tachycardia, œdema and congestive heart failure not infrequently precede death. Chronic "dry" beriberi with neurological manifestations follows much the same course as multiple peripheral neuritis from any cause, despite intensive B₁ therapy. Recovery is slow and the condition persists for many months. In some cases muscular weakness is permanent or there may be persistent flaccid paralysis due to nerve cell degeneration. After improvement or recovery patients who return to their polished rice diet are liable to relapse and sooner or later die of the disease.

Treatment.—**PROPHYLACTIC.**—Prophylactic measures consist in providing a balanced dietary adequate in B₁, i.e. 1 to 2 mg. daily. An allowance of 10 to 15 I.U. (international units) or 3.3 to 5.0 micrograms per 100 calories of food intake suffices for most purposes. Any condition which increases the metabolic rate requires an increase in vitamin B₁. These include (1) a diet high in starch, sugar or alcohol, (2) fever and (3) hyperthyroidism. In institutions where polished rice or white bread is the main article of dietary, under-milled or parboiled rice and whole-wheat flour should be substituted. The addition of cooking soda to vegetables should be avoided, since boiling in the presence of alkali destroys B₁, though heat alone does not. The importation of milled rice to communities with beriberi should cease.

CURATIVE.—Rest and dietary are all-important factors in recovery, and the introduction of crystalline vitamin B₁ (aneurine hydrochloride: thiamine hydrochloride) has revolutionised treatment in acute beriberi with cardiac involvement.

Crystalline vitamin B₁.—In ordinary cases this drug is administered orally, but the intravenous route is indicated (1) in severe and fulminating cardiac cases, (2) when there is reason to believe absorption is defective and (3) in liver disease. The optimum oral dosage remains to be determined, but 5 to 10 mg. daily for mild cases and 20 mg. daily for moderately severe cases should prove adequate. In severe cases, especially those with cardiac features, 20 to 50 mg. should be given each day by the intravenous route for the first 2 weeks, followed by a similar dosage daily taken by the mouth. In fulminating cardiac cases 100 mg. may be immediately injected and this should be repeated until relief is obtained, after which the dose may be reduced.

Careful nursing and absolute rest in bed are essential, and when there is right-sided cardiac failure venesection is of definite value. Small feeds containing Marmite should be given 2-hourly. Subsequently a low carbohydrate diet rich in B complex and adequate in other vitamins is advisable. Yeast, Marmite, wheat germ, rice polishings, wholemeal flour, barley, oatmeal, liver, kidneys and other glandular organs serve as a satisfactory source of B₁. Orange and tomato juice and, where possible, milk, butter, eggs and cream should also be included in the dietary of such cases.

In infantile beriberi the mother should receive vitamin B₁ treatment, and artificial feeding substituted for natural feeding or a healthy wet-nurse employed. Vitamin B₁ should be administered intramuscularly in adequate dosage, and the 2-hourly feeds reinforced with Marmite.

The efficacy of B₁ in acute fulminating beriberi and its relative ineffectiveness in

the ehronic polyneuric form suggests its main therapeutic effect is on the cardiovascular system and not the peripheral nervous system. Where there is polyneuritis rest is essential until the pulse is normal in all respects. Crystalline vitamin B₁ may be given orally in addition to a well-balanced diet reinforced with Marmite, brewer's yeast, etc. Where the lower limbs are involved a cradle should be put over the feet, while splinting may be necessary to prevent muscular contracture. After the more acute symptoms have subsided massage and electrical treatment may help to restore the circulation and muscle tonus. If the patient has lost postural sensation in the lower limbs re-education may be necessary during convalescence; sometimes in chronic "dry" beriberi ataxia persists after recovery of muscular power.

In all types of beriberi it is most important to treat intercurrent disease which is not infrequent.

PELLAGRA

Synonyms.—Mal de la Rosa; Mal del Sole; Maidismus; Psilosis pigmentosa; Malattia della Miseria; Asturian Leprosy; Alpine Scurvy.

Definition.—Pellagra is a chronic relapsing disease occurring especially in maize eaters, probably due to a deficiency in certain factors, especially those contained in the vitamin B₂ complex, i.e. riboflavin (B₂), pyridoxin (B₆ or adermin) and nicotinic acid (B₃). Clinically, it is characterised by buccal and gastro-intestinal disturbances, psychical and nervous features, and a symmetrical eruption especially affecting areas of skin exposed to the sun's rays or to friction.

Ætiology.—Pellagra (*pelle*, the skin; *agra*, rough) prevails endemically in the southern states of the U.S.A., lower Egypt, Turkey, Roumania, the Balkans, Spain and Italy, and has been reported from India, China, Japan, parts of Africa, Mexico, West Indian Islands and elsewhere. People of any race, age or sex are susceptible, and the malady is more common amongst the poorer classes. The incidence of the disease is greater in the spring. It occurs particularly amongst maize eaters, and in poorer communities living on cereals containing a low protein content or protein of low biological value. Following the work of Elvehjem on canine black tongue, nicotinic acid (B₃) and its amide have been found to clear up the early dermal changes and mucous membrane lesions in pellagra and to relieve many symptoms referable to the central nervous system. Certain coenzymes contain nicotinic acid amide (Warburg and von Euler), and severely ill pellagrins usually have a low coenzyme content in the blood (Vilter and Spies). It has been suggested that an interference with general cellular metabolism may result from a deficiency of available respiratory enzymes. When infection or hyperthyroidism increase the oxidative activity of the body and when the enzymes which facilitate such activity are wanting owing to a deficiency of their precursors, a deficiency syndrome follows. Other factors in the B₂ complex, i.e. riboflavin (B₂) and pyridoxin (B₆), as well as proteins, are also essential in preventing pellagra and probably have a closely interrelated function (see pp. 457, 459). Sydenstricker suggests that vitamin deficiency leads to changes in the gastric mucosa, liver and central nervous system and that some unidentified factor present in normal gastric and liver preparations may play an ætiological rôle; he reports that the administration of normal gastric juice often relieves the pellagrous syndrome, and that though gastric juice from pellagrous patients contains Castle's intrinsic factor, it is often lacking in this other factor, as well as HCl. Sporadic cases of true pellagra occur in alcoholics or are secondary to disease of the alimentary tract. They arise from malabsorption of pellagra-preventing factors or from deficiencies in the dietary prescribed. Irrespective of whether the development of pellagra follows poverty, erroneous dietary habits, dietary idiosyncrasies, organic disease, chronic alcoholic addiction, or some combination of these factors, the lesions, symptoms and methods of treatment are essentially the same (Spies).

Pathology.—Emaciation is marked and the internal organs, including the heart and spleen, are small and atrophic. Skin lesions consist of an initial erythema involving the superficial layers, terminating later in a true exfoliative or exudative dermatitis, associated with pigmentation. Stomatitis and glossitis with ulceration of the tongue, denudation of its epithelium and ultimate atrophy may ensue. The jejunum is congested and atrophic, and small superficial ulcers involving the jejunum, ileum, colon and rectum are described. The mesenteric glands may be enlarged. Demonstrable pathological changes in the nervous system are generally slight, but there may be a subacute combined degeneration of the cord involving the posterior and lateral tracts, and especially Clarke's column (Wilson). Degeneration of the anterior-horn cells in the lumbar region, and subacute inflammation of the ganglion cells in the posterior roots are described, while Briauchi recorded meningeal thickening and adhesions, atrophy of the cerebrum, and hydrops of the ventricles and sub-arachnoid space. More than 50 per cent of pellagrins show achlorhydria which is histamine-fast, but Castle's intrinsic factor appears to be secreted normally by the pyloric glands and megalocytic anaemia is rare. The total white count is generally normal in uncomplicated cases, there is often a lymphocytosis, and some degree of secondary anaemia is common. The cerebrospinal fluid exhibits no abnormality.

Symptoms.—The exact incubation period is unknown, and it should be realised that prodromal symptoms may recur over long periods before the classical oral or dermal features develop. In this stage a definite history is most important in making a correct diagnosis. Generally there is a history of having lived for a long period on (1) maize or other cereals poor in protein of high biological value, or (2) a diet high in fat and carbohydrate, and poor in proteins and vitamins, such articles as red meat, eggs, milk, fish, fresh vegetables and fruit being lacking.

Prodromal symptoms.—These include anorexia, loss of weight and strength, dyspepsia, flatulence, vomiting, sensations of burning or discomfort in the epigastrium, constipation or diarrhoea, insomnia, headache, palpitation, vertigo, numbness, forgetfulness, nervousness, mental irritability and mental confusion. Later, characteristic involvement of skin, alimentary tract and nervous system may supervene, but all three systems are not necessarily affected in any one pellagrin, while the sequence and the severity of the symptoms show considerable variation in individual cases.

Alimentary features.—The glossitis and stomatitis which usually appear early in the disease are diagnostic. In the early stages the tip and sides of the tongue are red and swollen, later the whole organ becomes fiery red (beet tongue) and inflamed, with lateral indentations from the teeth. Deep ulcers may develop on the sides and tip, while the dorsum becomes covered with a thick grey membrane, perhaps containing Vincent's organisms. A similar condition may involve the buccal mucous membrane, palate, gums and the mucous cutaneous surface of the lips. Hot, spiced and acid foods increase the ptyalism and the burning sensations felt in the tongue, pharynx, oesophagus and stomach. Other symptoms include nausea, vomiting and abdominal discomfort, flatulence and distension, especially after food. The bowels may act normally or be even constipated in the early stages, persistent diarrhoea being characteristic only of the advanced cases. In the latter the stools are non-fatty in type, diarrhoea occurs at all hours, and is often associated with colicky pain and tenderness. Sigmoidoscopy may reveal a proctitis. Associated vaginitis and urethritis are not uncommon.

Skin lesions.—Their distribution is on the back of the hands, wrists and forearms, the dorsum of the feet, the face, neck, upper part of the chest, under the breasts and in the perineal region—in short, over those areas directly exposed to the sun's rays or friction. Commencing as an erythema resembling a severe sunburn, there is redness, swelling and tension of the skin, followed by itching, burning and possibly hch formation, while later, a deeper dermatitis develops with desquamation and exfoliation. Pigmentation and thickening of the dermis result, but finally atrophy

supervenes, the skin becoming wrinkled, inelastic and thinned. Pathognomonic features of pellagrous eruptions are their absolute symmetry and their sharply demarcated pigmented borders—the hyperkeratotic border of Merk. Angular stomatitis, cheilosis and scrotal dermatitis are not infrequent and are manifestations of riboflavin deficiency.

Nervous system.—The early mental symptoms, which are often regarded as functional, include depression, apprehension, irritability, headache, insomnia and bilateral burning sensations involving the extremities or other parts of the body. Later these mental symptoms are accompanied by rigidity, tremor of the tongue, coarse tremors of the limbs and head, athetoid movements and cramp; while numbness and paralysis of the extremities are common. The reflexes which at first are generally increased, later become decreased, and finally are often entirely absent. The gait may be spastic or ataxic, and cord involvement or peripheral neuritis due to associated B₁ deficiency may be factors in the production of the neurological picture. If improperly treated, insanity often results. Retardation of growth occurs in children, but fortunately neurological complications are not common in them.

The course of the disease is generally afebrile and characterised by definite attacks alternating with remissions extending over many years unless a proper diet be maintained.

Diagnosis.—In classical pellagra the glossitis, stomatitis and the characteristic skin lesions make the diagnosis easy, but these features occur only in the well-established disease and it is the subclinical cases or those presenting vague prodromal manifestations which are so important to recognise early. A reliable history of dietary deficiency is important, and the rapid amelioration of gastro-intestinal and mental symptoms following nicotinic acid therapy will confirm the diagnosis. The urinary test for nicotinic acid excretion devised by Harris and Raymond may clinch the diagnosis in doubtful cases. Atypical pellagra may be confused with sprue or ergotism, while erythema multiforme and dermatitis venenata may cause difficulty.

Prognosis.—In endemic pellagra if patients receive modern treatment and a maintenance diet adequate in vitamin B₂ complex and good biological protein, the mortality should be low. In the past, about 40 per cent. have been estimated to develop mental trouble, and many of these died in asylums. Fever is an unfavourable sign, and in the absence of intercurrent disease occurs either as a terminal event or in the fulminating form known as typhoid pellagra, which is characterised by intense prostration, tremor, muscular rigidity, convulsions and death. In secondary pellagra, the prognosis depends on rectification of a faulty diet and treatment of the underlying alimentary trouble.

Treatment.—**PROPHYLACTIC.**—The addition to a pellagrin's diet of red meat, milk, eggs and substances rich in vitamin B₂ complex, e.g. brewer's yeast and Marmite, will prevent the disease.

CURATIVE.—Rest in bed, a high calorie, nutritious diet low in carbohydrate but rich in protein, and foodstuffs containing vitamin B₂ complex are desirable. The diet should include fresh milk, lean scraped red meat, liver, canned salmon, tomato juice, fresh fruit and vegetables. Articles which have been found to possess curative value when given in large dosage include brewer's yeast (75 to 100 g. daily), Marmite (30 to 60 g. daily), wheat germ (250 to 300 g. daily), ventriculin (200 g. daily) and liver extract (75 to 100 g. daily). The discovery of the curative effects of adequate doses of nicotinic acid on many of the manifestations of pellagra has revolutionised the treatment of the disease. The drug is administered by the mouth, in tablet form and in divided doses, the daily dosage ranging from 200 to 1000 mg., 500 mg. being generally effective. After 10 days the dosage may be decreased. Flushing, burning and itching, nausea, vomiting and colic may follow, especially if the drug is given in large dosage on an empty stomach. Nicotinic acid also stimulates gastric activity and acid secretion, and is liable to elicit a mild histamine-like type of reaction. The

mucous membrane lesions, including pellagrous glossitis, stomatitis, vaginitis, urethritis and proctitis, are healed and bowel function restored to normal, the early erythematous lesions are blanched, while the early and late mental relapse symptoms are greatly benefited. The chronic skin lesions, however, are not cured by nicotinic acid therapy. Associated symptoms of peripheral neuritis are not relieved by nicotinic acid, but both pain and numbness disappear after daily injections of 50 to 100 mg. of crystalline vitamin B₁ (Spies).

Riboflavin is indicated if there is scrotal dermatitis, angular stomatitis or cheilosis; the oral dosage is 5 to 15 mg. daily. No toxic effects have been described following oral administration.

NUTRITIONAL MACROCYTIC ANÆMIA

Synonyms.—Tropical Megalocytic Anæmia. Pernicious anæmia of Pregnancy.

Definition.—A severe nutritional anæmia, megalocytic in type, especially affecting pregnant women in hot climates and responding specifically to liver extract, Marmite or folic acid therapy. Non-hæmolytic and hæmolytic types are encountered.

Ætiology.—It is an unconditioned deficiency disease affecting both sexes, though it is specially common in women during the child-bearing period owing to the super-added nutritional demands of pregnancy and lactation. It occurs mainly in the tropics and subtropics and is associated with poverty and a low calorie diet which is predominantly vegetarian and poor in good biologic protein. It has been reported from India, China, Africa, Macedonia, British Guiana and Puerto Rico. In Macedonia it is prevalent in the refugee population whose diet is poor in animal protein while in South India it occurs in rice eaters. A similar nutritional macrocytic anæmia can be produced experimentally in monkeys fed on the same sort of diet as human sufferers from the disease. It is now known that nutritional macrocytic anæmia is not due to lack of extrinsic factor as was suggested originally by Castle. Probably it arises from deficiency of some other factor (Wills' factor) associated with good biological protein and contained in autolysed yeast and crude liver but not in highly purified liver extract; it has not been identified with any known constituent of B₂ complex. Possibly Wills' factor is an activator or co-enzyme in an enzyme system in which liver principle plays an important part (Wills). Its relationship, if any, to folic acid remains to be determined.

Hæmolytic nutritional macrocytic anæmia arises as a similar condition complicated by chronic malaria; the spleen is greatly enlarged and frequently the liver also. Probably some of the abnormal red cells produced by megaloblastic erythropoiesis undergo hæmolysis in the blood-stream; others are phagocytosed by an irritated and hypertrophied reticulo-endothelial system resulting from repeated malaria infections. In these cases reticulocytosis is almost always present, hyperbilirubinæmia is characteristic and those cases in which intravascular hæmolysis is occurring yield a positive Schumm's test due to the production of methæmalbumin (Fairley).

Pathology.—In the uncomplicated non-hæmolytic type the body is generally emaciated, fat is absent and the organs are pale and atrophic, the heart and liver especially being greatly reduced in size. Red marrow due to megaloblastic hyperplasia fills the long bones but as in sprue the tibia may sometimes show both red and aplastic marrow with a curious gelatinous appearance (Wills). The picture is really one of pan-hæmopoietic dystrophy with megaloblastic erythropoiesis with the production of Ehrlich's polychromatic megaloblasts, disturbances of the myeloid series with the production of macromyeloid cells, and abnormalities of the megakaryocytes. This is reflected in the peripheral blood by the presence of megalocytic anæmia, leucopenia and thrombocytopenia. In the hæmolytic type the body is reasonably well nourished and bright-yellow subcutaneous fat is present. The liver and spleen are

enlarged and there may be an enlarged heart with fatty degeneration in the myocardium. There is generalised hypertrophy and hyperactivity of the reticulo-endothelial cells which may contain malaria pigment and phagocytosed red cells. Fine hæmosiderin deposits in the parenchymal cells of the liver and spleen and a decrease of lymphoid tissue in the latter organ in which the Malpighian bodies have disappeared. Hæmorrhages may be found in the skin, mucous membranes and serous membranes. Panmyelopathy of the bone marrow is present. Basophilic and polychromatic megaloblasts are common but ripening sufficient to produce a really pink cytoplasm with a finely stippled primitive nucleus is not common. The reticulo-endothelium lining the marrow sinusoids is the ultimate source of erythrocytes, leucocytes and platelets and it is probable that both defective production of liver principle due to lack of Wills' factor and malaria are exerting a deleterious influence on the reticulo-endothelium in the hæmolytic type of nutritional macrocytic anæmia.

Symptoms—In the uncomplicated *non hæmolytic* type the symptoms are essentially those associated with a grave anæmia. The patient often first seeks advice for cardiac palpitations, giddiness, shortness of breath, weakness on walking and physical fatigue. Sore tongue, anorexia, vomiting, flatulence, abdominal distension and diarrhoea may be complained of, and fever or cough may or may not be present. Diarrhoea is variable and in some outbreaks is absent altogether. If present it is generally enteric in type, the stools being watery in consistency, brownish in colour and showing no excess of fat. Physical examination generally reveals pale mucous membranes, a low blood pressure, a rapid pulse and perhaps hæmic cardiac murmurs. Later frank congestive cardiac decompensation may ensue. The blood picture resembles that of pernicious anæmia with megalocytes and often nucleated red cells present in the blood smear. Red cell counts as low as 500 000 to 1,000,000 erythrocytes per cmm may be found. The colour index generally exceeds unity. The mean corpuscular volume is increased, and the Price-Jones curve shows a shift to the right and an increased variability in mean corpuscular diameter. Thrombocytes are decreased, leucopenia is common, the reticulocytes are not increased, the serum bilirubin values are normal and the fractional test meals show that, unlike pernicious anæmia, the oxyntic cells retain their power of secreting HCl after the administration of histamine. Petechial hæmorrhages in the skin and mucous membranes and signs of mild neuritis are occasionally found but spinal cord involvement does not occur.

In the *hæmolytic* type of tropical macrocytic anæmia, certain features are superadded. The spleen is enlarged and hard but not tender while associated enlargement of the liver is not uncommon. Petechial eruptions involving the skin, epistaxis, bleeding gums or bleeding from other mucous membranes occur in about 25 per cent of cases, and are associated with thrombocytopenia. An icteroid tinting of the skin or conjunctivæ is not uncommon, while hyperbilirubinæmia and dark brown stools are characteristic findings. The blood picture resembles in many respects the megalocytic anæmia already described, but reticulocytosis is the rule, and megalospherocytosis may be found which is not the case in the *non hæmolytic* type. Leucopenia and thrombocytopenia are frequent findings.

Apart from cardiac decompensation, the more common complications in both types include uterine sepsis in the puerperium, *Bact. coli* infections of the genito-urinary tract and respiratory infections. In the hæmolytic type the increased pressure on the diaphragm exerted from below by the pregnant uterus and greatly enlarged spleen causes considerable respiratory embarrassment. Typical paroxysms of malarial fever at this late stage are rare and parasites are not demonstrable between attacks.

Diagnosis—An adequate hæmatological investigation is essential in diagnosis. The *non-hæmolytic* type has to be distinguished from other megalocytic anæmias. It differs from pernicious anæmia in that HCl is secreted in response to histamine injections and spinal cord complications are absent. The atrophic, distended abdominal panetes, the marked loss of weight and the bulky pale fatty stools so characteristic

of tropical sprue are not observed in tropical macrocytic anaemia. The hæmolytic type clinically resembles acholuric family jaundice, but there is no family history, the corpuscular fragility is not increased to hypotonic saline solutions, and the anaemia is of an entirely different type in the two diseases.

Prognosis—Balfour estimated the death rate as 40 per cent before the introduction of liver therapy. With modern treatment and in the absence of complications patients whose condition is diagnosed at a reasonably early stage should recover completely. The non hæmolytic type responds more readily to treatment than the hæmolytic type.

Treatment—**PROPHYLACTIC**.—Prevention depends on the adoption of a well-balanced diet containing adequate amounts of protein of good biological value and vitamin B₂ complex.

CURATIVE—Uncomplicated cases of non hæmolytic type generally respond to Marmite (Wills) in a dosage of 30 grammes daily, to liver extract by the mouth equivalent to 1 lb of fresh liver daily, or to daily injections of 2 ml of injection of liver (Campolon type). Excellent results are also reported following the administration of folic acid 10 mg daily. Maximal reticulocytosis develops about the seventh to ninth day, and provided treatment is maintained satisfactory blood regeneration follows.

In the hæmolytic variety, or where complications exist, the anaemia is frequently very refractory and even much larger daily doses of Marmite (60 grammes) or parenteral liver extract (6 to 8 ml) are by no means always satisfactory, in severely ill patients, it is often advisable in addition to parenteral liver therapy to give repeated blood transfusions in order to tide the patient over the critical period before specific therapy initiates the hæmopoietic response. More recently it has been reported that the proteolysed liver extract Hepamino (1 oz) and also folic acid (10 mg) daily elicit an excellent hæmopoietic response in refractory megaloblastic anaemias associated with pregnancy (Davidson and Davis). Successful termination of labour and the cessation of lactation decrease the nutritional demands on the body and may result in spontaneous cure, but it is important to remember that skilled medical and nursing attention during the puerperium and the daily examination of the patient for the onset of complications such as cardiac failure and pulmonary infections are very necessary. Throughout treatment a nutritious diet containing meat, eggs, milk and foods rich in vitamin B₂ complex is desirable.

N HAMILTON FAIRLEY

PROTEIN DEFICIENCY

Since most cereal foods contain enough protein to supply most of the bodily needs when sufficient calories are ingested, protein deficiency rarely results from dietetic insufficiency without an accompanying deficit of calories. Some of these proteins are deficient in some of the essential amino acids and have been called second class proteins but it has been shown that a small addition of first class protein supplies adequate amounts of these missing amino acids, so that the biological value of the mixture is high. In certain areas where roots such as tapioca supply an appreciable portion of the total calorie intake, protein deficiency without calorie deficiency may occur.

Ætiology and Pathogenesis—In those parts of the world where food is generally available in adequate quantities protein deficiency occurs mainly as a result of conditions which prevent adequate food intake such as anorexia nervosa or obstructions of the œsophagus, or which interfere with absorption. Abnormalities of the digestive organs, such as idiopathic steatorrhœa, chronic pancreatitis and the results of a variety of surgical mutilations may all result in protein deficiency, and may

produce a similar picture to that found resulting from a dietetic deficiency. Liver disease may interfere with protein synthesis, and conditions with massive proteinuria such as the nephrotic syndrome may result in protein abnormalities, but produce a different picture from that of true deficiency. During infections and after any form of trauma in well-fed subjects, there is a considerable breakdown of protein and resultant loss of nitrogen; this is very difficult to prevent and may occur even when the protein intake is much above normal. It seems to be part of the bodily reaction which occurs as a result of trauma and is probably mediated by overaction of the adrenal cortex. In extensive burns the situation is greatly intensified, since, in addition to the loss just described, there is a considerable direct loss of protein in seepage from the burned area.

Symptoms and Signs.—It is difficult to separate the symptoms and signs of deficient protein intake from that of semi-starvation. Unlike acute starvation, where ketosis is prominent and hunger after a day or two is absent, long-standing under-nutrition is not associated with ketosis (provided about 150 g. of carbohydrate per day are ingested), and hunger and thoughts of food are a dominant feature of the mental make-up; for all else there is apathy and depression. Muscle wasting is very evident and this is associated with weakness and, most strikingly, with great lack of endurance.

Bradycardia, hypotension, a small heart and slight anaemia also occur and examination of the serum proteins may reveal them to be low, a finding, however, which is not always present, even in the presence of famine oedema. The basal metabolic rate is also lowered but this is more apparent than real, because in undernutrition there is a high extracellular fluid volume relative to total body weight; nevertheless it does seem that there is a slight reduction in the metabolic rate of the tissues themselves. More striking, however, is the decrease in the overall daily expenditure of energy which may be only about half that of the normally fed individual. A loss of about 30 per cent. of the lean body-weight is the maximum which can occur without loss of life.

Treatment.—Where the deficiency is the result of some pathological condition this must, of course, be corrected. Where the deficiency has resulted simply from lack of adequate food it is advisable to increase the amount of food gradually, since cases of congestive heart failure have occurred when large amounts of food have been given to semi-starved individuals. The main necessity is to supply adequate calories, about 3000 to 3500 being the level ultimately to be achieved, with at least 300 of them in the form of protein. There is a rapid return to normal weight, but it may take as long as a year before full functional normality is attained.

GEORGE A. SMART.

Ætiology—Kwashiorkor is generally considered to be the result of severe protein deficiency, usually arising from the intake of a diet low in protein and high in carbohydrate. Although the pathogenesis of the syndrome is not understood it has been suggested that on the whole the organs and tissues affected first and most severely are those with the highest turnover of protein, i.e., the gut, mucosa, liver and pancreas (Waterlow). Secondary deficiencies of individual vitamins may develop. Many cases are complicated by the effects of malaria, helminth infestations (especially hookworm) and severe bacterial infections. These complications are not considered to be direct ætiological factors, although they may considerably modify the clinical picture. The syndrome occurs in their absence.

Pathology—The œdema is sometimes said to be associated with the low serum albumin content, but there is no obvious direct relationship. There is some evidence of salt retention.

Changes in the skin vary enormously from patient to patient. Patchy change in pigmentation commonly occurs, which is often indistinguishable from that arising from genetic factors. There may be scattered areas of both hyper- and hypopigmentation. Where dermatoses are present the histological changes resemble those described in deficiencies of the particular vitamins concerned.

Changes occur in the texture and pigmentation of the hair. In the latter case, the custom has been to refer to "depigmentation" but since there appears to be qualitative as well as quantitative change, the term "dyspigmentation" is used here.

THE LIVER—Post mortem examination and biopsy commonly reveal fatty degeneration and infiltration, first seen in the periphery of the lobules. The cells of the whole lobule may be involved. During successful treatment the fatty changes have been seen to regress. Various degrees of fibrosis and sometimes gross cirrhosis may be seen, especially in patients who have had the syndrome for some time. These changes are believed to be late developments of the same process which results in the earlier fatty changes, i.e., the essential protein deficiency.

THE PANCREAS—Degenerative changes have been described, varying from atrophy of the acinar cells with diminution in content of granules to hyaline changes, dilated tubules and periacinar, perilobular and sometimes periductal fibrosis. In advanced cases large areas of acinar tissue may be replaced by fibrous tissue. The islets may also be affected.

Considerable attention has been paid recently to these pancreatic changes. It has been suggested that they may be the essential pathological lesions responsible for the development of the syndrome, including the fatty changes in the liver. Examination of the duodenal contents in severe cases has revealed reduction in amounts of amylase, trypsin and lipase, normal quantities being restored after successful treatment.

OTHER TISSUES—Atrophic changes in the salivary glands have been described. Muscular atrophy is often considerable, although it may be masked clinically by œdema. Some workers have reported atrophic changes in the intestinal wall. Lesions of the kidneys occur in some cases, the most striking features of which are glomerular hyalinisation and pericapsular fibrosis.

Symptoms and Signs—The syndrome comprises some combination of the following features: (i) retarded growth, especially evident during late breast feeding and weaning, (ii) muscular wasting and œdema, (iii) alterations in skin and hair pigmentation and in hair texture. Various forms of nutritional dermatoses may occur but are not invariably present. Biopsy or necropsy reveals the liver changes described above, these are presumed to be present in some form in all cases. Mortality is high in untreated cases.

The syndrome is most easily described as it occurs in the infant. Trowell draws a striking picture of the mother "unwrapping a miserable imp who immediately

grizzles and cries and avoids the light " The child is apathetic, rarely resists examination and tends to stay where it is put instead of wandering off like a healthy child. The state of the child is one of "peevish mental apathy"

It is retarded for its age in both weight and stature. It may not, however, look emaciated since the subcutaneous fat is often considerable and the prevailing œdema may give a superficial appearance of good nutrition. The essential muscular wasting may become obvious only as the œdema subsides during treatment. It is prominent in the occasional case in which the œdema is minimal.

Changes in the texture and colour of the hair occur in all races, but are probably best seen in the African in whom the black curly coarse wool may be replaced by reddish grey or white straighter silky hair, sometimes over the whole head, sometimes only over the temples and vertex. Dyspigmentation may occur without change in texture.

In the original description of kwashiorkor, dermatosis was present. It is now generally agreed that dermatoses, although extremely common, are not necessarily an essential part of the clinical pattern. The commonest skin change is one of pigmentation, which may occur without apparent change in skin texture. In many cases the development of hypo or hyper-pigmentation probably represents the initial change in the development of more serious skin lesions. The commonest form of the latter appears on areas exposed to irritation such as the napkin area, the back, the buttocks, thighs etc. The areas usually affected in pellagra, such as the hands and face, escape.

Early lesions are described by Trowell as "sharply defined black varnished patches which rapidly enlarge". The affected hyper-pigmented skin becomes dry, cracks, scales and peels off, sometimes in "large enamel paint" plaques, half an inch or more across. The area beneath is depigmented and is easily damaged and infected especially in the "napkin area". The general picture has been called "crackled" or "crazy pavement" skin. Many cases show an almost universal dry scaling dermatosis which is often particularly prominent in the lower legs. Other forms of skin change include the so called elephant skin, the skin being thickened fissured and either hyper pigmented or often unchanged in pigmentation. Bullous changes associated with secondary infection and ulceration in the pelvic region have also been described. The black scaling peeling dermatosis is easily recognised and its association with the kwashiorkor syndrome is generally accepted. On the other hand the origin of some of the other skin changes mentioned is often difficult to decide and factors such as exposure, and particularly onchocercal and other skin infections must be carefully excluded as far as possible before accepting such lesions as related to the malnutrition syndrome. The skin lesions respond well to treatment.

Most patients are obviously œdematous. The œdema is characteristically soft and easily pitted. It is most obvious in the legs and extends into the genitals and thighs and sometimes the buttocks. The arms especially the forearms are often involved. Oedema of the face especially around the eyes and nose is common.

Most infants with kwashiorkor are notably pot bellied, a feature which is often exaggerated by the way they sit upright, with their legs bent in front of them. There may be some œdema of the belly wall and evidence of free fluid in the peritoneal cavity. The liver is nearly always palpable. The firm edge may be felt an inch or more below the costal margin, there is usually no tenderness.

Gastro intestinal disorders are common. Most patients suffer from indigestion and diarrhoea is very common. The infant passing numerous semi liquid or yellowish stools containing undigested food. There may be some steatorrhœa, with the passage of bulky soft offensive stools also containing undigested food.

Various signs of vitamin deficiencies are common. Chedosis angular or general stomatitis changes in the eyes including Bitot's spots and xerophthalmia may be present. Photophobia is common.

grizzles and cries and avoids the light". The child is apathetic, rarely resists examination and tends to stay where it is put instead of wandering off like a healthy child. The state of the child is one of "peevish mental apathy".

It is retarded for its age in both weight and stature. It may not, however, look emaciated since the subcutaneous fat is often considerable and the prevailing *œdema* may give a superficial appearance of good nutrition. The essential muscular wasting may become obvious only as the *œdema* subsides during treatment. It is prominent in the occasional case in which the *œdema* is minimal.

Changes in the texture and colour of the hair occur in all races, but are probably best seen in the African, in whom the black curly coarse wool may be replaced by reddish, grey or white straighter silky hair, sometimes over the whole head, sometimes only over the temples and vertex. Dyspigmentation may occur without change in texture.

In the original description of kwashiorkor, dermatosis was present. It is now generally agreed that dermatoses, although extremely common, are not necessarily an essential part of the clinical pattern. The commonest skin change is one of pigmentation, which may occur without apparent change in skin texture. In many cases the development of hypo- or hyper-pigmentation probably represents the initial change in the development of more serious skin lesions. The commonest form of the latter appears on areas exposed to irritation, such as the napkin area, the back, the buttocks, thighs, etc. The areas usually affected in pellagra, such as the hands and face, escape.

Early lesions are described by Trowell as "sharply defined black varnished patches . . . which rapidly enlarge". The affected hyper-pigmented skin becomes dry, cracks, scales and peels off, sometimes in "large enamel-paint" plaques, half an inch or more across. The area beneath is depigmented, and is easily damaged and infected, especially in the "napkin area". The general picture has been called "crackled" or "crazy pavement" skin. Many cases show an almost universal dry scaling dermatosis which is often particularly prominent in the lower legs. Other forms of skin change include the so-called elephant skin, the skin being thickened, fissured and either hyper-pigmented or often unchanged in pigmentation. Bullous changes associated with secondary infection and ulceration in the pelvic region have also been described. The black scaling peeling dermatosis is easily recognised and its association with the kwashiorkor syndrome is generally accepted. On the other hand, the origin of some of the other skin changes mentioned is often difficult to decide and factors such as exposure, and particularly onchocercal and other skin infections must be carefully excluded as far as possible before accepting such lesions as related to the malnutrition syndrome. The skin lesions respond well to treatment.

Most patients are obviously *œdematous*. The *œdema* is characteristically soft and easily pitted. It is most obvious in the legs and extends into the genitals and thighs and sometimes the buttocks. The arms, especially the forearms, are often involved. *Oedema* of the face especially around the eyes and nose is common.

Most infants with kwashiorkor are notably pot-bellied, a feature which is often exaggerated by the way they sit upright, with their legs bent in front of them. There may be some *œdema* of the belly wall and evidence of free fluid in the peritoneal cavity. The liver is nearly always palpable. The firm edge may be felt an inch or more below the costal margin; there is usually no tenderness.

Gastro-intestinal disorders are common. Most patients suffer from indigestion and diarrhoea is very common, the infant passing numerous semi-liquid or yellowish stools containing undigested food. There may be some steatorrhoea, with the passage of bulky soft offensive stools, also containing undigested food.

Various signs of vitamin deficiencies are common. Cheilosis, angular or general stomatitis, changes in the eyes, including Bitot's spots and xerophthalmia may be present. Photophobia is common.

Anæmia is present in some degree, probably in all cases. Where there are no parasitic infections, the anæmia is mild and orthochromic. Ankylostomiasis, malaria and schistosomiasis all affect the final blood picture. The red cell count commonly lies between 2.5 and 3.5 million cells per c.mm. The cells are usually orthochromic. Where there is iron deficiency, for example, in the presence of heavy ankylostoma infestation, they may be hypochromic. In severe cases there may be some macrocytosis, probably due to the presence of reticulocytes. Megaloblasts are not present. The bone marrow response is normoblastic.

Serum albumin is low. This is regarded as a reflection of liver dysfunction. The globulins may or may not be increased.

The blood chemistry varies with the condition of the patient. Both chloride and fixed base may be reduced.

Liver biopsy will reveal the fatty or fibrotic changes described above depending on the stage of the syndrome and the length of its duration.

Course.—The development of the untreated case is steadily retrograde. The child becomes increasingly dull and apathetic; the retardation of growth continues; the gastro-intestinal symptoms, oedema and skin and hair changes progress, and various signs of vitamin and other deficiencies develop. There is a very high mortality in untreated cases. Nevertheless, the response to treatment is good in the vast majority unless the syndrome has progressed too far before treatment is commenced.

Diagnosis.—The combination of retarded growth, especially in infants during weaning or post-weaning, alterations in skin and hair pigmentation and oedema, usually with some grade of dermatosis establishes the clinical diagnosis. Biopsy of the liver revealing fatty or fibrotic changes confirms it.

According to some authorities a pre-oedematous stage of the syndrome exists, but the general view seems to be that the diagnosis of kwashiorkor should be confined to the oedematous stage. Some workers are critical of clinical diagnosis in the absence of evidence obtained by liver biopsy. Dermatitis and vitamin deficiency signs are not essential for the diagnosis. Signs of deficiency of a particular vitamin, for example A or B, are often very common complicating factors of the syndrome in a particular area and account for some of the wide variation of clinical patterns described.

Where the diagnosis is being made in groups of children, it is strengthened by heavy mortality amongst untreated cases.

Prognosis.—Prognosis is bad in the untreated case. Mortality ranges from 30 to 40 per cent. and occasionally even higher. Many infants will die within a day or two of being first examined and placed on treatment. Once treatment has been successfully started, however, the prognosis rapidly improves. Mortality in properly treated cases should be less than 5 per cent.

Treatment must be continued over a long period and be carefully supervised, otherwise relapses are common.

Milder untreated syndromes in children may progress into adult life as a state of subnutrition in which one or more of the essential features of kwashiorkor may be emphasised.

Treatment.—To be effective treatment must be carefully controlled. It consists essentially of restoring the nutrition balance and dealing with concomitant parasitic or other infections.

Advanced cases require intravenous protein hydrolysates or serum. Severely ill infants should be given 100 ml. human plasma daily for the first 10 days. The intravenous route is preferable, but if this is impossible the serum may be given into the bone marrow or subcutaneously.

Patients who can be treated orally should be given frequent small meals throughout the day. The diet should be high in protein and low in fat. Most cases tolerate fat extremely badly. Milk is the most satisfactory diet. Skim milk or lactic acid milk seems to produce the best results. The average case in infants should be given

at least 1 pint, and if possible 2 pints, of skim milk daily to begin with. If the child refuses milk at the beginning of treatment it should be coaxed to accept it, and, if necessary, food should be withheld for a few hours until it does. Powdered milk (not reconstituted) may be given several times a day by spoon in addition, to increase the protein intake.

A good mixed diet is gradually substituted for milk as the patient improves, and may replace the milk after several weeks.

Vitamins, if introduced, should be given in the form of cod-liver oil or vegetable extracts. Purified vitamins are seldom necessary and may be harmful.

It may be necessary to give iron. Very anæmic cases require immediate transfusion. A small transfusion often helps the progress of even moderately anæmic patients. Where there has been severe loss of fluid and salt from diarrhoea and vomiting, parenteral administration of isotonic saline or glucose saline may be required.

Parasitic infections should be diligently sought out and treated. Bacterial infections, even when they appear trivial, should be treated, if possible, with antibiotics. Malaria should be treated immediately. Quinine and sulphonamides should be used sparingly, however, in the early stages. Synthetic antimalarials are preferred. Some workers advocate small daily doses of proguanil in any case in endemic areas, even when malaria parasites are not seen.

The treatment of helminth infections, which tends to be toxic, should be deferred until the patient is regarded as strong enough.

The usual lipotropic factors such as methionine are not in themselves of any appreciable benefit in dealing with the fatty liver lesion.

BRIAN MAEGRAITH.

SECTION VII

DISEASES OF THE ENDOCRINE GLANDS

DISEASES OF THE PITUITARY GLAND

APART from its own special functions, the pituitary gland has a stimulating trophic effect on most of the other ductless glands, which latter tend to atrophy after removal of the pituitary gland (hypophysectomy). The influence, however, is reciprocal and hyper- or hyposecretion of the other endocrine glands influences the activity of the pituitary. The hypothalamus, on either side of the third ventricle, contains many nerve nuclei which are connected with the posterior pituitary gland. The anterior pituitary receives hypothalamic chemical stimuli by vascular channels.

The posterior lobe secretes two hormones, pitressin and oxytocin. The former has a vaso-pressor action, is anti-diuretic and produces an increased urinary excretion of chloride. The latter, oxytocin, produces contraction of the pregnant uterus. The pars intermedia secretes the melanophore expanding hormone.

The anterior pituitary gland appears to secrete 10 or more hormones, but it is uncertain whether they are all distinct chemical substances. It has been postulated that one hormone may have different actions under varying physiological circumstances. Description is facilitated by assuming the existence of separate hormones :

1. Growth or somatotrophic hormone.
2. Lactogenic hormone. This initiates and maintains mammary secretion. Experimental evidence also suggests the existence of a mammogenic hormone, which produces development of mammary acini and ducts even in the absence of ovaries.
3. Thyrotrophic hormone (thyrotrophin). This produces (a) hyperplasia of the thyroid gland and hypersecretion of thyroxine; and (b) exophthalmos, even after thyroidectomy.
4. Gonadotrophic hormone (gonadotrophin). This factor has been chemically separated into two components, Prolan A and Prolan B, which under certain conditions produce different gonadotrophic reactions. Thus, Prolan A stimulates development of the Graafian follicles and of the spermatic tubules; whereas Prolan B produces luteinisation of mature follicles, or of the theca of immature follicles, and hyperplasia of the interstitial cells of the testis.
5. Diabetogenic complex. Pituitary extracts produce hyperglycaemia, glycosuria and ketonuria in some species of animals, intact or partially depancreatised. The complex has two definite components—(a) adrenocorticotrophic (see below), and (b) somatotrophic. F. G. Young has shown that pure growth hormone (somatotrophic) is powerfully diabetogenic in animals and that its action is independent of the adrenal glands. There may be a third factor in the diabetogenic complex, not as yet chemically separated.
6. Insulotrophic hormone. The evidence for this is suggestive rather than conclusive. It may be an initial or inherent action of growth hormone in certain species under appropriate conditions.
7. Adrenocorticotrophic hormone (corticotrophin, A.C.T.H.). This is measured by restriction of adrenal cortex size and weight or by decrease of ascorbic

acid content of adrenal cortex, both tests carried out in the hypophysectomised animal. It stimulates increased secretion both of androgens and glucocorticoids by the adrenal cortex and there may be two corresponding types of the hormone. The glucocorticoids or 11-oxysteroids are diabetogenic and ketogenic.

ACROMEGALY

Definition.—Acromegaly is a condition due to a hypersecretion of the growth hormone of the anterior pituitary gland. It is characterised by enlargement of the hands and feet, and of the bones and cutaneous tissues of the face, and of the thoracic and abdominal viscera. It is frequently superimposed on gigantism.

Ætiology.—The disease occurs at any age but usually before 40, and in both sexes. There is a mild familial type. The immediate cause is an excessive secretion of the growth hormone.

Pathology.—The primary lesion is an adenoma, or hyperplasia, of the eosinophil cells. Secondary enlargement of the adrenal cortex and the thyroid are often present. The testes and ovaries are usually atrophic in the later stages. The islets of the pancreas may be hyperplastic in the initial phases, and later undergo atrophy. Diffuse lymphoid hyperplasia is frequent. All the viscera are enlarged.

Symptoms.—The patient may first seek advice because of increasing size of the hands and feet, or of a blunting and distortion of facial features, or visual disturbance due to a pituitary tumour. The latter is associated with optic atrophy, bitemporal hemianopia, progressive loss of vision and severe headaches. Ocular palsies may result from pressure on the third, fourth or sixth nerve.

The enlargement of the extremities is partly due to bony enlargement and thickening, but there is also overgrowth of the soft tissue. The vault of the skull may be somewhat thickened, but considerable bony overgrowth is more common in the base of the skull and in the facial bones. The overgrowth of the lower jaw leads to prognathism and spreading of the teeth. The vertebrae undergo changes, and kyphosis and scoliosis are common. The soft tissues of the face, nose and lips undergo hypertrophy, which together with the bony changes, may transform the facial appearance. The skin and subcutaneous tissue are thickened, and the sebaceous and sudoriferous glands hypertrophied, producing a greasy perspiring skin. The hair too is thick and greasy, and may be abundant over the trunk. Enlargement of the tongue leads to difficulty in articulation, and enlargement of the larynx produces a deep voice. Speech is also sluggish and memory poor. The general behaviour may be characterised by apathy and lack of initiative. Generalised muscular hypertrophy may initially be associated with great strength, but later weakness and atony result. The heart is enlarged, but hypertension or hypotension may occur.

Complications and Sequelæ.—(1) Sex Function. Impotence in the male, and amenorrhœa in the female, are common complications, caused by destructive encroachment of the eosinophil cells on the gonadotrophic basophil cells. (2) Thyroid. A non-toxic colloid goitre, sometimes nodular, is found more frequently than a hyperplastic goitre with thyrotoxicosis, and this fact throws doubt on the thyrotrophic origin of thyrotoxicosis. Myxœdema may develop in the later stages. (3) Adrenals. They are frequently enlarged and contain adenomata. This enlargement indicates stimulation by the adrenocorticotrophic hormone. Hirsutism results in both sexes. (4) Diabetes Mellitus. This disorder is present in a small proportion of patients; but some degree of intermittent or chronic hyperglycæmia with glycosuria, in the absence of diabetic symptoms, may be detected in some 50 per cent. It can be attributed both to the somatotrophic and the adrenocorticotrophic hormones. (5) Mental Changes. Depression, irritability, negativism, melancholia, mania and delusional insanity are possible complications.

Diagnosis.—The increase in size of hands and feet, and thickening and blunting of the facial features, with prognathism, makes diagnosis easy, especially if gigantism is already present. Osteitis deformans is a bony disorder which distorts the vault of the skull and does not often affect the facial bones. In acromegaly, radiographic examination may reveal an enlargement of the sella turcica, which if associated with optic atrophy or bitemporal hemianopia, indicates a pituitary tumour. A raised serum phosphorus is indicative of active acromegaly. The urine may show raised values for adrenal glucocorticoids and 17-ketosteroids.

Prognosis.—The course is gradually progressive, with intermittent phases of apparent arrest of the pituitary hyperfunction. These phases may be prolonged over many years. As myxœdema may follow exophthalmic goitre, so hyperactivity of the pituitary may be succeeded by hypoactivity with secondary hypofunction of the thyroid and adrenal glands.

Treatment.—If there is progressive involvement of the optic nerves, with danger of complete blindness, the treatment is surgical removal of the pituitary tumour. Otherwise irradiation of the pituitary region should be tried first, and relief results in some 50 per cent. The initial dose should be on the small side to guard against secondary hypopituitarism. Testosterone and œstradiol in large doses have some influence in depressing pituitary overactivity. Complications such as thyrotoxicosis, myxœdema, impotence and amenorrhœa are treated appropriately. True diabetes mellitus will need dietetic regulation and insulin, but symptomless glycosuria can be ignored.

GIGANTISM

This is due to excessive secretion of the pituitary growth hormone before the epiphyses have united. It may be followed by acromegaly. Muscles and bones are usually strong in pituitary gigantism, and weak in eunuchoidism, excessive height being due to delayed epiphyseal closure. Adolescent gigantism with mild acromegaly in males, however, may be associated with delayed puberty, gynœcomastia, delayed epiphyseal closure and absence of muscle strength.

The treatment of pathological gigantism is the same as for acromegaly, namely, irradiation of the pituitary gland, or surgical removal of a pituitary neoplasm. Inhibition of pituitary activity by large doses of testosterone, or œstradiol, may be of some benefit.

INFANTILISM

Synonym.—Levi-Loraine Syndrome.

Definition.—Infantilism consists of a retardation of somatic growth and sexual development with failure to attain adult dimensions and sexual characteristics. The term was first used by Loraine in 1871 in connection with a case of infantilism associated with tuberculosis. It was later applied by Levi (1908) to hypopituitarism beginning in childhood. Brissaud extended the term to include infantilism associated with hypothyroidism (Brissaud's syndrome), but this is a more complicated and less well-defined disorder.

Ætiology and Pathology.—Usually in life there is no gross lesion and necropsies are rare, since the uncomplicated condition is not incompatible with good health. Experimental and biological evidence indicates a deficiency of pituitary eosinophil cells (growth hormone), and of basophil cells (gonadotrophic). Occasionally a third ventricle tumour, or pituitary craniopharyngioma, or chromophobe adenoma may be the cause. Tuberculosis, congenital or rheumatic heart disease, cœliac disease or any chronic childhood illness may be the cause of infantilism.

Symptoms.—In childhood, the patient is perfectly formed but somatic growth is much below the usual rate. Development of the primary and secondary sexual characteristics at puberty does not occur, and the genital organs remain infantile

throughout adult life. The condition, however, is not absolute, and varying degrees of sexual development are met with. Although the epiphyses tend to remain open long after the normal time of closure, the ultimate height is well below normal, as the secretion of growth hormone is deficient. Intellectual development is usually normal and sometimes above normal standards, but emotional development and the behaviour pattern tend to remain immature. The patients are usually slender and have graceful limbs, ankles, wrists and fingers. The skin and hair are of smooth silky texture, and the general appearance is becoming.

Diagnosis—The condition should be differentiated from other forms of dwarfism.

Prognosis—This depends upon the time at which treatment is commenced, but in general hormone therapy can only produce a trend towards normality. Health and normal function, other than sexual, is maintained even in the absence of any treatment.

Treatment—In contrast with the dramatic effect in the experimental animal pituitary growth hormone is not effective in most cases of infantilism and does not even cause nitrogen retention. This is a paradox, as yet unsolved. Methyl testosterone, 25 mg daily by mouth, produces nitrogen retention with skeletal and muscular growth. In the female or in young children methyl androstenediol is preferable, since its androgenic effect is far less than that of methyl testosterone. Insulin is now known to be chondrotrophic in the hypophysectomised rat, although to a less degree than growth hormone, but this may justify its therapeutic application in selected cases. Gonadotrophins and oestrogens will stimulate sexual development.

DWARFISM

Definition.—A condition of subnormal height well below the normal range. It is the opposite of gigantism. Although no other abnormality may be present, the use of the term is also extended to include a variety of conditions, of which deficient height is only one feature.

Ætiology and Pathology—The essential feature is a deficiency of pituitary eosinophil cells and of their growth promoting hormone. The condition is quite comparable to that found in a strain of congenital dwarfed mice, in which the dwarfism and deficiency of eosinophil cells follows a Mendelian recessive genetic distribution in successive families. Occasionally in man a pituitary or other intracranial destructive neoplasm may be the cause. Cushing's syndrome in children is associated with dwarfism since cortisone inhibits cartilage proliferation. In sexual precocity there is initial acceleration of growth, but the ultimate height is usually subnormal because of premature union of the epiphyses.

Symptoms—In uncomplicated cases there are no features other than retardation of growth. In some patients, especially girls, there is premature union of epiphyses at puberty, e.g. 12 years of age. If, on the other hand, sexual development is infantile the condition is that of infantilism (see above). In Fröhlich's syndrome, adiposity is an essential feature. Dwarfism may also be a feature of Simmonds's cachexia, if the condition is due to a pituitary craniopharyngioma commencing in childhood. Progeria (meaning prematurely old) is a name given by Hastings Gilford in 1904 to a rare condition comparable to Simmonds's cachexia in childhood, and associated with an old, wizened countenance, infantile sex organs, dwarfism, alopecia, absence of breasts and a parchment like skin. The condition is probably of pituitary origin, but its exact pathology is uncertain. Ovarian agenesis (Turner's syndrome) is due to a congenital absence, or failure of maturation, of rudimentary ovaries, but the associated dwarfism is due to a pituitary defect. Webbed neck, cubitus valgus and other congenital stigmata may also be found in this condition. Urinary gonadotrophins are present in excess.

Diagnosis.—With simple failure of growth, or in infantilism, the relative proportion of arms, legs and trunk may be normal. Non endocrine causes of dwarfism are rickets, renal rickets, fragilitas ossium, coeliac disease, pancreatic disease, von Gierke's glycogen disorder, vitamin deficiency, cardiac disease and achondroplasia. In achondroplasia a familial condition of defective endochondral ossification, the arms and legs are short compared with the body (human dachshund).

Prognosis.—Where the epiphyses are ununited, and treatment is started early with a potent growth hormone preparation, the prognosis is fair, but the response is sometimes poor.

Treatment.—As in infantilism, *vide supra*

SIMMONDS'S DISEASE

Synonyms.—Pituitary Cachexia, Hypopituitarism, Panhypopituitarism, Sheehan-Simmonds's Disease

Definition.—A disorder due to destruction or atrophy of the anterior pituitary gland, and manifested by cachexia, anorexia, subnormal metabolism and hypogonadism.

Ætiology.—The disease is more common in women since the commonest cause is atrophy of the anterior pituitary resulting from a local vascular lesion during the puerperium. Multiparæ are especially prone. It may, however, occur at any age and in either sex associated with a pituitary or parapituitary tumour.

Pathology.—Simmonds's original case showed atrophy and fibrosis of the anterior pituitary gland as a result of an embolus in the main artery in a fatal case of puerperal fever. The vascular lesion is, however, more commonly thrombosis of the pituitary veins, following severe uterine hæmorrhage at parturition. Suprasellar cystic tumours and chromophobe adenoma are other important causes and rarely malignant metastases, tuberculosis, syphilis and exanthemas. An unusual ætiological occurrence is simply diminution in the relative number of eosinophil cells. As in the case of hypophysectomy, the gonads, thyroid and adrenal cortex are hypoplastic or atrophic. The viscera are diminished in size in contrast to the splanchnomegaly of acromegaly.

Symptoms.—Weakness, amenorrhœa, anorexia and loss of pubic hair are cardinal features. Cachexia is by no means constant and occasionally patients do not even lose weight. Impotence occurs in the male. In both sexes the secondary sexual characteristics, e.g. pubic, facial and axillary hair, are lost, and the eyebrows and hair of the scalp also become thin and lustreless, or disappear. The skin is pale and dry, and may become wrinkled, giving a senile facies, known as progeria. The lower jaw may become atrophic (opposite of prognathism), and the teeth decay and fall out. The low metabolism, e.g. —40 per cent, is manifested by a subnormal temperature and hypersensitivity to cold. Bradycardia and hypotension are usual features. The blood sugar is low and insulin sensitivity increased. Spontaneous hypoglycæmic attacks occur and may be fatal. Anæmia, relative lymphocytosis, eosinophilia and a raised sedimentation rate are not uncommon.

If the disorder begins in childhood, the lack of growth hormone results in failure to grow, although the epiphyses remain ununited in adult life. There is also failure of sexual development. Panhypopituitarism in childhood, however, is more appropriately called infantilism than Simmonds's disease.

Complications.—Pulmonary tuberculosis may follow prolonged inanition. Apathy, inertia and somnolence are characteristic and may progress to melancholia, with disorientation in time and place. Optic atrophy results from tumours. The Snapper-Witts syndrome consists of hypopituitarism, achlorhydria, hypochromic or hyperchromic anæmia, subacute combined degeneration and alopecia.

Diagnosis.—The well developed syndrome cannot escape recognition if the disorder is kept in mind. Cachexia is not always a feature. Minor and incomplete

manifestations are more easily missed, but not if the possibility of the disorder following a puerperium in which there is severe hæmorrhage and (or) infection is remembered. Migrainous headaches can occur even in the absence of a pituitary or parapituitary tumour, but radiographic examination of the sella turcica and examination of the fundi for optic atrophy should not be omitted. The condition is often mistaken for myxœdema, but without justification, and the response to thyroid alone is never adequate, as it is in myxœdema.

There are many features in common with Addison's disease, but pigmentation in Simmonds's cachexia is either absent, or slight, and is never present in the mucous membranes. Anorexia nervosa in the later stages may show many of the features of Simmonds's cachexia, suggesting perhaps an inhibition of pituitary activity via the hypothalamus. A similar mechanism may explain examples of incomplete Simmonds's disease following shock or psychic trauma. Inanition may itself, however, result in hypotension, hypothermia, hypoglycæmia, hypometabolism and bradycardia. The initial and fundamental cause of anorexia nervosa is psychogenic, and there are essential differences in the clinical history and manifestation of anorexia nervosa and Simmonds's disease. Thus anorexia nervosa usually occurs in young adults more often in females, and it is possible to elicit a history of psychic trauma, shock, disappointment or emotional upset. In contrast to the apathy of Simmonds's cachexia these patients are restless and perform feats of activity far beyond their apparent strength, loss of sexual hair, if any, is rarely extreme, in contrast, the trunk and perhaps the face is covered by diffuse downy hair. The 24-hourly output of 17 ketosteroids is low in Simmonds's cachexia, e.g. 0.5 mg (normal 5 to 12 mg), and the insulin sensitivity test (intravenous injection of insulin 0.05 units per kg body weight) shows a rapid fall of blood sugar to low levels, e.g. 30 mg per 100 ml, and a delayed recovery curve (hypoglycæmic refractoriness). In myxœdema, the output of ketosteroids is very low, but the fall in blood sugar after intravenous insulin is somewhat retarded, although the subsequent elevation may also be retarded. The Kepler test for adrenal function (see p 509), often shows as low an index in Simmonds's disease as in Addison's disease.

Prognosis—There is usually progressive deterioration, but patients with minor manifestations following pregnancy may recover spontaneously. Treatment is beneficial, but it is not easy to provide complete substitution therapy, and the cessation of therapy is often followed by relapse. Patients are usually sterile, but should pregnancy supervene and parturition be normal, clinical recovery may result from hyperplasia of the pituitary remnant.

Treatment—Administration of adrenocorticotrophic hormone is effective in the form of long-acting corticotrophin (A.C.T.H. Gel), 40 units intramuscularly daily. Injections are troublesome and allergic reactions may occur. Cortisone by mouth, 25 to 50 mg daily, is more convenient, given with methyl testosterone by mouth e.g. 25 mg daily and thyroideum siccum gr 1 or more daily. Methyl testosterone and thyroid, even without cortisone, bring about considerable improvement. Cortisone is valuable in diminishing the risk of sudden hypoglycæmia. If thyroid alone is given, it may be poorly tolerated and acute adrenal crisis may develop. If a patient with recognised Simmonds's disease become comatose, hypoglycæmia must first be suspected and intravenous glucose should be given at once. Coma may, however, occur without hypoglycæmia or obvious adrenal crisis. It is called hypothermic crisis, and hot baths may revive the patient.

FRÖHLICH'S SYNDROME

Synonyms—Dystrophia Adiposo Genitalis, Babinski-Fröhllich's Syndrome.

Definition—Failure of sexual maturation, associated with dwarfism and adiposity

Ætiology.—This is usually destruction of the anterior pituitary gland by a craniopharyngioma with involvement of the adjacent hypothalamus causing adiposity. It occurs in either sex. Fröhlich's original case was a boy of 14 with a craniopharyngioma.

Pathology.—The lesion is usually a craniopharyngioma. More rarely it is a chromophobe adenoma and sometimes a gross lesion cannot be discovered.

Symptoms.—It is important to realise that the condition is very rare. The failure of development of sexual and secondary sexual characteristics is absolute and not merely delayed. The adiposity involves the face and trunk, and the limbs are slender. Such adiposity, as judged by photographs, was not of any severity, in the original cases of Fröhlich and Babinski. For clarification, it is better to regard inadequate somatic growth as an essential part of the syndrome and, as a corollary, not to make the diagnosis in patients whose height is normal or above normal. The complexion is pallid as in pituitary deficiencies and not plethoric.

Complications.—Rarely the syndrome is complicated by the additional features of retinitis pigmentosa, mental deficiency, polydactylism and familial incidence. It is then called the Laurence-Moon-Biedl syndrome.

Diagnosis.—The three main features of the disease are failure of sexual development, dwarfism and adiposity. An enlarged sella turcica and optic atrophy give support to the diagnosis but are not essential. By definition the diagnosis cannot be made before puberty, in the absence of an intracranial neoplasm, except as a speculation.

Prognosis.—The condition does not improve in the absence of treatment.

Treatment.—Craniopharyngiomata are treated surgically. It is logical to prescribe pituitary gonadotrophic hormones supplemented by thyroid; boys should also receive methyl testosterone and girls œstrogens and progesterone.

DIABETES INSIPIDUS

Definition.—Diabetes insipidus is a disturbance of water balance, characterised by polyuria and polydipsia, and it is due to a destructive lesion of the posterior lobe of the pituitary gland, or of the adjacent part of the hypothalamus.

Ætiology.—The condition is sometimes familial. It is due to a deficient secretion of the antidiuretic hormone by the posterior lobe of the pituitary. This results from destruction of the lobe, or any interruption of its normal connection with the supraoptic nucleus of the hypothalamus. Such a lesion is followed by degeneration of the pars nervosa, but not of the pars intermedia.

Pathology.—In the majority of cases there is no obvious cause. It is sometimes due to trauma, a vascular lesion, syphilis, tuberculous meningitis, a primary or metastatic brain tumour, a pituitary or parapituitary neoplasm involving the posterior lobe, or Hand-Schüller-Christiansen's disease. The condition may also follow shock, via the hypothalamic mechanism.

Symptoms.—The symptoms are polyuria and polydipsia, with the passage of large quantities of urine, e.g. 12 litres in 24 hours, of pale colour, and low specific gravity, e.g. 1002. The polyuria leads to disturbed sleep and anxiety. The patient loses weight and strength, and may become very emaciated and even bedridden if untreated.

Diagnosis.—Hysterical polyuria may be difficult to differentiate apart from the hysterical background. There is a tendency in this condition, however, for the polyuria to be more marked during the daytime and the patient may sleep throughout the whole night, whereas the polyuria of diabetes insipidus is most troublesome at night. The hysterical patient remains in reasonably good health in spite of the poly-

dipsia and polyuria Some individuals have a familial hypersensitivity to caffeine and, if much tea or coffee is drunk, they have polyuria and frequency Diabetes mellitus is easily distinguished by hyperglycæmia and glycosuria In chronic nephritis the urine may be voluminous and of constantly low specific gravity, but it contains albumin and renal casts A Wassermann reaction will exclude tertiary syphilis Radiographs of the skull, and examination of the optic disks and visual fields should exclude pituitary and parapituitary tumours The Hand Schuller-Christian disease is congenital and familial and characterised by exophthalmos, a large liver and spleen, yellow-tinted skin and irregular areas of xanthomatous infiltration in the skull

Prognosis—The disease is protracted and if treatment is inadequate the patient becomes emaciated and dies from intercurrent infection

Treatment—The best replacement therapy consists of Pitressin tannate in oil, 5 mg in 1 ml, injected intramuscularly, the effect lasting 24 to 48 hours This is preferable to aqueous Pitressin, 10 or 20 units in 1 ml given 2 or 3 times in 24 hours Powdered Pitressin, 50 mg insufflated or snuffed intranasally, may be effective in milder cases or used as supplementary therapy Pallor, headaches, intestinal cramps and precipitate bowel action may complicate treatment when large doses are necessary

DIABETES TENUIFLUUS

Definition—A condition of supernormal secretion of the posterior pituitary antidiuretic hormone, manifested by diminution in the volume of urine excreted and an absence of thirst Tenuifluus means "flowing slenderly", and the condition is the opposite of diabetes insipidus (tasteless urine) The latter condition might be better termed diabetes multifuus (copious urine—flowing greatly)

Ætiology and Clinical Features—It is due to excessive secretion of the antidiuretic hormone of the pars nervosa of the pituitary, is probably rare as an uncomplicated entity and on the comparatively few occasions that it has been observed it has appeared to be part of a pituitary syndrome It may be found with pituitary or parapituitary tumours with Frohlich's syndrome and with other varieties of pituitary adiposity Acromegaly may be associated either with diabetes insipidus or with diabetes tenuifluus, and one may give place to the other according to the phase of the disease In one such case of the latter, Ellinger, Hare and Simpson demonstrated, for the first time, that there was an excess of antidiuretic hormone in the cerebrospinal fluid The daily intake of fluid was small, and the output of urine even smaller the difference apparently being explained by an obviously excessive perspiration in contrast with the dry skin of diabetes insipidus It is interesting to note that irradiation of the pituitary gland resulted in a normal and balanced fluid intake and output and a disappearance of excessive perspiration and of the excess of antidiuretic hormone from the cerebrospinal fluid

Water retention with resulting extensive œdema may occur in hysteria or the anxiety neuroses, possibly via hypothalamic stimulation of the pars nervosa Pre-menstrual water retention is not infrequent, the mechanism being via the posterior pituitary or the adrenal mineral corticoids Low caloric diets in adiposity may cause phases of water retention

Complications—E I Jones described a syndrome, in a man of 26, which he attributed to hyperactivity of the posterior lobe of the pituitary gland The main features were hypertension, hyperchromic anæmia, achlorhydria and impaired carbohydrate tolerance Melanophore expanding, vasopressor and antidiuretic substances were present in the urine (Noble and others)

Diagnosis—An abnormally small daily excretion of urine in the absence of

cardiac or renal disease suggests diabetes tenuifluus, especially if accompanied by excessive perspiration for which no ordinary cause is obvious.

Treatment.—Irradiation of the pituitary gland may be beneficial.

DISEASES OF THE THYROID GLAND

The essential function of the thyroid gland is to control the metabolic rate of the body but it also has an important influence on growth, sexual function, the cardiovascular system, nitrogen and carbohydrate metabolism and fluid balance. The essential principle, thyroxine, was isolated by Kendall in 1919; shown to be an amino acid derived from tyrosine, 3 : 5 : 3' : 5'-tetraiodothyronine, by Harington in 1926; and synthesised by Harington and Barger in 1927. The *lævo*-rotatory form, L-thyroxine, is ten times more active than the *dextro*-rotatory form. In 1952, a substance $2 : 5 : 3' : 5'$ -L-triiodothyronine was found to be a normal constituent of plasma by Gross and Pitt-Rivers in England, and Roche, Lissitzky and Michel in France, and its activity in animals and man to be some three times that of L-thyroxine. It has been separated from thyroglobulin and is probably the form of thyroid hormone that is active in the tissues. Thyronine has a similar basic structure to thyroxine. It is quite inactive without its iodine atoms. Thyroglobulin is a protein of large molecular weight and is the form in which thyroxine is stored in the colloid of the thyroid gland. Diiodotyrosine is present in thyroglobulin and is an intermediate product in the natural synthesis of thyroxine but is itself inactive.

The normal thyroid gland contains 5 mg. of thyroxine and 8 mg. of iodine. Intake requirements of iodine for equilibrium are estimated as 15 micrograms per day per adult and 50 micrograms for a child. Protein-bound iodine in blood is a measure of the thyroxine content, the normal range being 4.0 to 8.0 micrograms per 100 ml., values being higher in thyrotoxicosis and lower in myxœdema. The average daily requirements of L-thyroxine in a completely thyroidectomised adult are 0.3 mg.; 0.1 mg. thyroxine is equivalent to 1 grain of *thyroideum siccum*. An inadequate intake of iodine produces goitre, due to an ineffective attempt by the thyroid to produce thyroxine. An old observation that cabbage produced goitre in rabbits, led to the discovery that thiourea and thiouracil are also goitrogenic and that they act by preventing the synthesis of thyroxine. Since iodine deficiency or thiouracil can produce ineffective thyroid hyperplasia without hyperthyroidism or with hypothyroidism, it is obvious that hyperplasia is not synonymous with hyperfunction. This explains some difficulties in interpreting the histology of pathological thyroid tissue. The administration of iodine causes a reduction in the degree of hyperplasia and of hyperthyroidism and increases the amount of colloid in the gland. This also influences the interpretation of pathological histology.

Pituitary thyrotrophic hormone causes hyperplasia and hyperfunction of the thyroid gland. Marine showed that subtotal destruction of the adrenal gland has a similar effect, and more recently it has been found that cortisone, conversely, inhibits thyroid function. Both these effects are mediated through the pituitary gland.

Clinically there are two main types of hyperthyroidism, exophthalmic goitre, and toxic adenoma. Hypothyroidism may result in cretinism, or myxœdema, according to whether the deficiency is already present at birth or develops after a period of normal thyroid function.

EXOPHTHALMIC GOITRE

Synonyms.—Graves's Disease; Parry's Disease; Basedow's Disease; Primary Thyrotoxicosis.

Definition.—Hyperactivity and hypersecretion of the thyroid gland, usually manifested by tachycardia, tremor, loss of weight, nervousness, sweating, exophthalmos, enlargement of the thyroid and raised basal metabolic rate.

Ætiology.—The disease is more common in females than males, in the ratio of 6 to 1. This is probably associated with the greater lability of the endocrine system in the former, as indicated by the not infrequent physiological transient enlargement of the thyroid at puberty, at menstruation and the menopause. The malady is commonest in the second and third decades, but it may occur in childhood or old age. Symptoms may first appear at puberty or the menopause.

Mental stress, anxiety, shock and sexual neurosis are often precursors of the disease, but a constitutional vulnerability of the thyroid to such stimuli is probable. The latter is also indicated by a familial predisposition. Infection aggravates pre-existing hyperthyroidism.

Pathology.—The cuboidal epithelial cells undergo hypertrophy and become columnar. They also divide and multiply (hyperplasia), and may project in folds into the follicles, giving a lacce-like pattern. The follicles are almost emptied of colloid unless iodine has been given. There is a generalised lymphatic hyperplasia and lymphoid infiltration of the thyroid itself. The thymus is usually enlarged. The liver may show areas of necrosis or atrophy, and is often depleted of glycogen. Experimentally, pituitary thyrotrophin will produce similar thyroid hyperplasia and a raised basal metabolic rate in guinea-pigs and man. Nevertheless, it has not been possible to demonstrate such a hormone in the blood of patients with hyperthyroidism.

Symptoms.—The excessive secretion of thyroxine has wide systemic effects, and also disturbs the nervous stability of the patient. Many of the symptoms appear to result from overactivity of the sympathetic nervous system.

Cardio-vascular system.—Tachycardia in some degree is invariable, and is usually associated with palpitation. Extra-systoles may be present, and if the disease is of long standing or in people over 40, auricular fibrillation is not infrequent. Capillary pulsation may be seen, and vasomotor instability is evidenced by a tendency to blush or the appearance of a characteristic patch of redness over the neck and upper sternum. The carotid and brachial vessels pulsate visibly and forcibly. The systolic pressure is usually raised and the diastolic is normal or diminished, resulting in an increased pulse pressure.

Nervous system.—There is a characteristic tremor of the hands, noticeable on being asked to hold out the hands, or in writing, or in lifting a cup. Anxiety is a frequent and almost invariable accompaniment of exophthalmic goitre. The patient is also restless and unstable, and finds it difficult to remain in one position for any length of time. Conversation too is desultory and, although there is often a hyperacuity of perception and conception, this is offset by an inability for sustained effort or concentration. Increased sensitivity and sensibility trouble the patient and her associates or family, and emotional distress is common. Occasionally psychotic manifestations develop, especially paranoia and acute mania, with suicidal tendencies, but rarely does this happen in the absence of a constitutional predisposition. Sweating is often excessive, manifested by the hot, moist handshake, and it may be soaking undergarments or bedclothes. Severe muscular weakness and wasting may be present, associated with excessive katabolism of muscular tissue and creatinuria. Myasthenia gravis, acute bulbar palsy and progressive muscular atrophy may be simulated.

Ocular signs.—Upper lid attraction is characteristic, giving a glint to the eye or a coquettish look when it is mild in degree, or a frightened stare in more severe cases. True exophthalmos is indicated by the appearance of sclera between the cornea and the lower lid, and by orbital bulging and tension. Exophthalmic ophthalmoplegia occurs with severe thyrotoxicosis, but also in middle-aged patients with euthyroidism (a term indicating normal thyroid function) or mild hyperthyroidism. The condition may at first be unilateral. The conjunctiva is swollen and congested and histological examination shows œdema and lymphatic infiltration of the ocular muscles and orbital contents. Exophthalmic ophthalmoplegia (malignant or progressive exophthalmos) is thought to be produced by the thyrotrophic hormone of the pituitary, which explains its occurrence with hypothyroidism after too radical thyroidectomy.

Thyroid gland.—This is almost invariably enlarged, although the degree is by no means proportional to that of the thyrotoxicosis. The enlargement usually affects both lobes, and not infrequently the isthmus. The swellings are smooth and roughly symmetrical, but one lobe may be larger than the other. Small degrees of enlargement may be missed unless the proper technique of palpation is observed. The thumb should compress the site of one lobe of the thyroid against the trachea, and the opposite lobe then becomes palpable to the thumb or fingers of the other hand. This procedure is best carried out with the patient lying flat without a pillow. A systolic bruit over the thyroid may be heard on auscultation.

Metabolism.—Increased basal metabolism is characteristic and is a good indication of the degree of thyrotoxicosis. The occasional near-normal value, with reliable technique, must be explained by the patient's previously normal metabolism being below average. There is a negative nitrogen balance with creatinuria, due to pathological breakdown of muscle tissue, the fat depots of the body tend to disappear and the serum cholesterol to be low, e.g. 90 mg. per 100 ml. Loss of fat is not always an essential feature and may sometimes be overcompensated due to an increased appetite.

The liver is depleted of glycogen, and transient or persistent glycosuria may appear. This rarely indicates true diabetes mellitus, which is not more common among thyrotoxic patients than among the rest of the population. Nevertheless, thyroxine is antagonistic to insulin. In thyrotoxic glycosuria, the resting blood sugar level is normal, but following 50 grammes of glucose there may be a high and prolonged blood sugar curve. In the absence of gastro-intestinal symptoms, or partial starvation, ketosis rarely occurs. There may be a negative calcium balance and, although the serum calcium is not raised, as in hyperparathyroidism, the renal excretion of calcium is not infrequently excessive. There results a decalcification of the bones, sometimes to a severe degree.

Other features.—Relative impotence may be present in the male, and amenorrhœa or scanty menstruation is common in females. Pigmentation is rare, and is usually confined to the orbital regions, but it may occasionally be diffuse. Premature whitening of the hair sometimes occurs. There are no characteristic blood changes, but a lymphocytosis may be present. Dyspepsia and diarrhœa may be troublesome features. Occasionally abdominal pain may be severe enough to simulate an acute abdomen, and on laparotomy acute congestion of the pancreas has been observed. Crises are an alarming feature of thyrotoxicosis, sometimes precipitated by infection, or occurring in the first few days after thyroidectomy, but often without obvious cause. There is an acute exacerbation of the condition, with manifestations predominantly cardiac, cerebral or gastro-intestinal, and patients may die unless the condition is promptly recognised and treated. Cerebral forms of crises are particularly dangerous, and are manifested by acute excitement and irritability, acute mania, delusions and hallucinations. There is also a comatose form.

Diagnosis.—When the classical features of tachycardia, exophthalmos, enlarged thyroid, tremor of the hands and loss of weight are present the diagnosis usually offers no difficulty.

"Masked" forms of hyperthyroidism, or "formes frustes", in which the presenting feature appears to indicate some other disease, may offer difficulty, but awareness of the possibility of hyperthyroidism usually prevents a mistaken diagnosis. Thus, it is important to look out for a possible thyroid basis in cases of auricular fibrillation, and it would seem that the latter may occur in paroxysmal form before the clinical picture of hyperthyroidism is well developed, while occasionally fibrillation may supervene some years after the disease is apparently arrested.

Loss of weight, sweating and rapid pulse may suggest pulmonary tuberculosis; or wasting combined with glycosuria give rise to a diagnosis of diabetes mellitus. The muscular wasting and weakness of hyperthyroidism may simulate the myopathies, or myasthenia gravis. The latter is an extremely rare complication of thyrotoxicosis, and is differentiated by the selectivity for groups of muscles and the response to neostigmine. Some patients are treated for an associated neurasthenia before the thyrotoxicosis is recognised. An overactive sympathetic nervous system at the climacteric may produce many features simulating thyrotoxicosis, but only a small proportion of such patients have true thyrotoxicosis. Neuro-circulatory asthenia may simulate hyperthyroidism, and the thyroid gland is often somewhat enlarged, but in the former the tachycardia is more dependent upon emotion and change of position, and the pulse-rate at rest, or when sleeping, is usually not raised.

In hyperthyroidism the basal metabolic rate is raised and the blood cholesterol is diminished. There is a high value for the protein-bound serum iodine, the uptake by the thyroid of radioactive iodine is increased and its urinary excretion during a 24-hour or 48-hour test period is reduced.

Course and Prognosis.—The natural course of the disease, in the absence of treatment, is progressively downhill, but waves of remission and exacerbation occur. Nevertheless, some patients recover spontaneously, or even become myxoedematous. The chief dangers are cardiac failure, intercurrent infection and mental disorder. The results of treatment are good. Although pathological upper lid retraction usually disappears following treatment, some degree of exophthalmos not infrequently persists.

Treatment.—Mild cases may respond to sedatives, rest and reassurance. To these may be added small doses of iodine, e.g. 5 min. of Lugol's iodine daily. This is not curative but it lowers the degree of thyrotoxicosis. Spontaneous recovery or even transition to myxoedema is possible.

Severe cases may be treated with subtotal thyroidectomy or with radioactive iodine. Pre-operative treatment with methyl thiouracil, or propyl thiouracil, has replaced pre-operative Lugol's iodine because it is more effective. Methyl thiouracil is given as a tablet, 200 mg. t.d.s., for some 14 days or until the basal metabolism is normal or the clinical features of thyrotoxicosis have largely disappeared, and no patient should undergo thyroidectomy before their thyrotoxicosis is so controlled. Methyl thiouracil is replaced by Lugol's iodine, 10 min. t.d.s., for some 7 days before operation, in order to minimise the tendency to congestion and hæmorrhage which it produces.

Methyl thiouracil may be used as an alternative to operation. It is then given as 100 mg. t.d.s. and the dose is gradually tapered off to 50 mg. once daily and stopped entirely 6 months after the symptoms have been completely controlled. The great disadvantage is the danger (2 per cent.) of agranulocytosis which may come like a bolt from the blue two days after a normal blood count. All patients are warned to stop tablets and report if malaise, sore throat or fever develops. Agranulocytosis is treated with corticotrophin (A.C.T.H.) and penicillin. The other disadvantages are

the persistence of the goitre, the tendency to relapse in some 50 per cent of cases and the prolonged uncertainty. Propyl thiouracil is alleged to be less liable to produce agranulocytosis. Thiouracil acts by blocking the synthesis of thyroxine in the thyroid gland. The resulting increased secretion of pituitary thyrotrophic hormone may initially aggravate the degree of exophthalmos and enlarge the existing goitre but amelioration of both may follow later.

Radioactive iodine is in the opinion of the writer, the treatment of choice, although warnings of the possibility of injury to the ovaries and late development of metallic carcinoma are still voiced but not substantiated. The bombardment of metallic tellurium in a cyclotron transmutes the tellurium into radioactive iodine, the principal isotopes being I^{130} (which loses half its activity in 12 hours) and I^{131} (which loses half its activity in 8 days). Radioactive iodine, I^{131} , which looks and tastes like stale water, is given in a single dose by mouth. It is selectively taken up almost entirely by the thyroid gland and then gives off electrons (beta rays) which cause atrophy of the hyperplastic gland. Clinical cure results after some 8 weeks, except for a persistent exophthalmos, but, if necessary, a second dose can be given after 3 months. Overdosage may result in myxœdema. The latter is very liable to occur if thyroidectomy is attempted after an initial dose, which was thought to be inadequate. Dosage is determined by preliminary tracer studies, measuring iodine uptake by the thyroid by means of a Geiger-Müller counter, and its urinary excretion, and by clinical estimation of the size of the goitre.

TOXIC ADENOMATOUS GOITRE

Synonyms—Secondary Thyrotoxicosis, Thyrotoxic Nodular Goitre

Definition—Hyperthyroidism associated with, and usually superimposed upon, a nodular goitre.

Ætiology—Thyrotoxic symptoms occur in some 15 per cent of nodular goitres. The cause is usually unknown, but occasionally iodine appears to provoke thyrotoxicosis in a quiescent gland.

Pathology—Plummer's term, Toxic Adenoma, might be thought to indicate a single adenoma but only rarely is this the case. More commonly multiple adenomas are found throughout the glands and apart from these, other areas of the gland may show hyperplasia indistinguishable from that found in exophthalmic goitre, as well as areas of colloid vesicles.

Symptoms—This condition can be differentiated clinically from exophthalmic goitre by the absence or mildness of upper lid retraction and exophthalmos, the absence of the general anxiety so characteristic of Graves's disease, the rarity of thyrotoxic crisis and the rarity of recurrence of thyrotoxicosis after thyroidectomy. It is also more likely to affect an older age group, namely over 40 years of age, and the brunt of the thyrotoxicosis appears to fall on the cardiovascular system. When the thyroid gland is obviously nodular to palpation, or when the goitre has been present for some years before thyrotoxic symptoms develop (i.e. secondary thyrotoxicosis) clinical differentiation from Graves's disease on either of these grounds is clear. In their absence, differentiation is relative rather than absolute and cannot necessarily be decided by thyroid histology, since the general hyperplasia of the thyroid in Graves's disease may be accompanied by microscopic adenomata and the nodular adenomatous goitre may contain areas of hyperplasia. Nevertheless clinical differentiation appears justifiable.

Prognosis—Inadequately treated the condition deteriorates rapidly and cardiac failure results. The response to thyroidectomy is excellent and the percentage of recurrence is less than 1 per cent.

Treatment—Thyroidectomy is indicated for large or grossly nodular goitres.

Others may be treated with radioactive iodine. The condition is not unresponsive to methyl thiouracil.

MYXŒDEMA

Definition.—A primary condition of hypothyroidism, associated with low basal metabolism, and manifested by sensitivity to cold, mental hebetude, loss of hair and mucoid infiltration of the skin and subcutaneous tissue. It does not include hypothyroidism secondary to pituitary hypofunction, and the term pituitary myxœdema is best avoided.

Ætiology.—Myxœdema usually occurs sporadically and without obvious cause, although there is occasionally a history of preceding infection. It is more frequent in women than men, in the ratio of 8 to 1, and is most common in middle age. Perhaps the condition in women is comparable to the cessation of ovarian function, which also takes place in the fifth decade. The disease, however, may have its onset in old age, or even in childhood—when it is known as juvenile myxœdema. There would also appear to be a constitutional predisposition, as several cases may occur in the same family. Myxœdema may follow partial thyroidectomy for thyrotoxicosis, or complete thyroidectomy for non-thyroid cardiac disease, the term *cachexia strumipriva* sometimes being given to post-operative myxœdema. Apart from operation or excessive radiation, myxœdema may arise spontaneously following chronic thyrotoxicosis. It may also occur endemically and usually with goitre, the ætiology being a relative or absolute iodine deficiency.

Pathology.—The thyroid is atrophic, and the secreting epithelium is largely replaced by fibrous tissue. The skin and subcutaneous tissue are infiltrated with a mucoid-like material, which was wrongly thought to be mucin, and hence the name myxœdema. There is an abnormal accumulation of extra-cellular and extra-vascular protein, the osmotic pressure of which leads to a transfer of saline from plasma to interstitial tissues. The mucoid infiltration may be widespread and implicate the nasal, pharyngeal, buccal and auditory mucous membrane, salivary glands, the larynx and the œsophagus. The kidneys are sometimes extensively involved, and there may be deposits in the vulvo-vaginal region. The heart and coronary vessels not infrequently show atheromatous changes, with some cardiac dilatation, but contrary to general belief, actual mucoid infiltration is a rarity.

Symptoms.—The onset is usually insidious, and at least half the patients have had the disease for some years before it is recognised. The general condition is comparable to hibernation, all the physical, metabolic and mental processes being sluggish and reduced much below the normal.

Integument.—The facies is pale and puffy, with baggy eyelids and a characteristic malar flush. There is thinning of the outer half of the eyebrows, and the hair of the head is dry and lustreless and falls out, sometimes with resulting patchy alopecia. The skin is dry and rough, and gives a swollen œdematous appearance, especially in certain regions, e.g. face, neck, supraclavicular areas, hands, legs and feet; but there is no pitting on pressure. In contrast to hyperthyroidism, obvious sweating is minimal or absent.

Cardio-vascular.—The pulse-rate is characteristically slow, e.g. 50, but there may be tachycardia with cardiac insufficiency. The blood pressure may be raised but not necessarily so. Angina sometimes occurs. Radiography usually shows enlargement of the heart, and in the electrocardiogram the voltage is low, with flattening or inversion of T waves.

Mental changes.—Apart from the psychoses, especially melancholia, which may complicate advanced or chronic cases, there are characteristic abnormalities of behaviour. The intellectual processes appear dimmed, and memory is poor. There is a noticeable latent period before questions are answered, and speech is slow, thick,

indistinct and rather toneless. The whole attitude is apathetic and lethargic, with a tendency to somnolence and even coma.

Metabolism.—The basal metabolic rate is usually of the order of -40 , the temperature is subnormal, and the patient hypersensitive to cold, being especially intolerant of the winter months. There is an almost constant hypercholesterolaemia, e.g. 380 mg., and the blood protein bound iodine is very low. The fasting blood sugar may be normal or slightly below normal, and there is apparently an increased carbohydrate tolerance in some patients. The injection of 4 units of insulin intravenously is followed by a slower rate of fall of blood sugar than occurs in normal individuals, although the subsequent rise in blood sugar is often retarded. Occasionally diabetes mellitus occurs as a complication of myxœdema, the pancreatic islets, as well as the thyroid, being atrophic. The urinary excretion of 17-ketosteroids is low because of secondary depression of pituitary adrenotrophic and gonadotrophic functions.

Inadequacy of adrenal function secondary to the thyroid deficiency is shown by a positive Kepler test and very low values for urinary 17-ketosteroids and 11-oxysteroids.

Blood.—There are three types of anæmia found in myxœdema: (1) Hypochromic low colour index anæmia. This variety responds to iron. It differs from other iron-deficiency anæmias, however, in the absence of microcytosis. (2) Hyperchromic megalocytic high colour index anæmia. This responds to liver, and is comparable to pernicious anæmia. (3) Simple hyperchromic macrocytic high colour index anæmia. It differs from Addisonian anæmia in the absence of megalocytosis and failure to respond to liver. Neither does it respond to iron, but thyroid has a specific effect, although a gradual one. The three types may be associated with achlorhydria, which is not uncommon, but type (3) is a specific thyroid deficiency anæmia. Either of the first two types may, on treatment with iron or liver respectively, change into the last type (simple hyperchromic). It is generally assumed that thyroid is a direct hæmopoietic agent essential for maturation of red cells, but the partial atrophy of the erythron in hypothyroidism may be an adaptation to the diminished need of the tissues for oxygen.

Other features.—Constipation is common, in contrast to the diarrhœa of thyrotoxicosis. Similarly, appetite and thirst are diminished. Deposits of mucoid material may impair hearing, smell, taste and swallowing. There may be menorrhagia, and in the male relative or absolute impotence is not infrequent. Vague generalised pains may be a feature, and some recognise a subthyroid form of chronic rheumatism.

Diagnosis.—Even though well-developed myxœdema presents a characteristic clinical picture, it is perhaps the most frequently missed endocrine disorder, and this is certainly true of the early or slight cases. The best method of avoiding this is constantly to bear in mind the existence of the disorder, especially when dealing with menopausal women. Sluggish mental response, with thick dry skin and loss of hair, failure of memory and sensitivity to cold are characteristic.

Many patients will first be seen by the psychiatrist, although the disease must have been present for some time. Others will present themselves to the gynaecologist on account of menorrhagia. Again, the appearance of the patient may lead to the diagnosis of anæmia, confirmed by blood examination, but the other features should not be missed. The pale, puffy face with baggy eyes also resembles the facies of parenchymatous nephritis, and albuminuria may complicate myxœdema if the kidneys are involved in the mucoid infiltration; a further resemblance between the two conditions is the high blood cholesterol. Myxœdema may be difficult to differentiate from hypothyroidism in Simmonds's cachexia, both having a low B.M.R. and sensitivity to cold. In the latter condition, however, mucoid infiltration of the skin is rare, the skin being thin and wrinkled, and thyrotrophic hormone will raise the metabolism and uptake of radioactive iodine to normal, whereas it has no such effect in myxœdema, the atrophied thyroid gland being unable to respond.

Localised myxœdema may paradoxically be a complication of hyperthyroidism,

usually in a recurrent or post operative phase. The B M R may have changed from above to below normal, but is sometimes still raised. Thick œdematous plaques appear on the front of the shins, or the whole leg may be thickened. The overlying skin is often wrinkled and hairy, and the skin may itch or burn. Nodular lesions may also involve the face, arms, back or scrotum. The pathogenesis of localised myxœdema is uncertain, for the response to thyroid is poor.

Course and Prognosis—In the absence of specific treatment the course is slowly but progressively downhill, and many patients end in the asylum. The response to treatment, however, is usually excellent though by no means necessarily so if a psychosis has already developed.

Treatment—The specific treatment in myxœdema is thyroid, given as L. thyroxine 0.3 mg daily, or thyroideum siccum, gr 3 daily. It is, however, prudent to commence with smaller doses, especially because of the extra strain that may be thrown on the heart by the increase in metabolism and the rate of circulation. A heart that was previously adequate may be unable to meet the extra demand, and cardiac failure or angina may supervene if the initial dosage is too large. In the long run, however, thyroid in appropriate dosage has a beneficial influence on the cardio vascular system. If an untreated myxœdematous patient is first seen with some cardiac insufficiency and a rapid pulse (in contrast with the usual bradycardia) there may be hesitation to give thyroid, but in small and gradually increasing dosage the drug has a beneficial if paradoxical effect the cardiac rate diminishing as the heart and coronary circulation improve. With the more usual bradycardia, thyroid has the effect of increasing the pulse rate, and should this rise above 76 the dose of thyroid should be reduced. More exact criteria of dosage may be obtained by estimations of the basal metabolic rate or the blood cholesterol. It is useful to remember that thyroid, even if administered intravenously as a single dose of thyroxine, requires 24 to 48 hours to begin to act, has its maximum effect at the end of a week, and continues to act for several weeks. There is therefore no point in giving thyroid more often than once daily, and a cumulative effect may be guarded against by missing one week in four. Thyroxine has no advantage over the dried gland, and its intravenous administration is not without danger as the initial reaction may be alarming e.g. nausea, vomiting, angina, pyrexia, aching muscles, loss of hair and peeling skin. Hypothermic coma may be treated by placing the patient in a warm water bath, or by any other measures which will raise the body temperature.

Hypochromic anaemia will respond to iron, simple hyperchromic anaemia to thyroid and true Addisonian anaemia to liver or vitamin B₁₂.

CRETINISM

Definition—This is a condition of hypothyroidism beginning in fetal life. In contrast, childhood myxœdema is superimposed on a normal infancy and early childhood. The disorder is endemic or, more rarely, sporadic in incidence.

Ætiology—The endemic form occurs in goitrous areas, the mother usually having a goitre. Iodine deficiency of the soil and water, and other theories are discussed in the Goitre section. No cause for the sporadic form is known. The sex incidence in both varieties is about equal.

Pathology—In the endemic form, the goitre is usually the nodular adenomatous variety. In sporadic cretinism, a goitre is rare, the thyroid being atrophic with flattened irregular epithelial cells, small alveoli and connective tissue overgrowth.

Symptoms—The untreated cretin is mentally deficient, apathetic and somnolent, and tends to lead a vegetative existence. All the stages of childhood development are retarded the fontanelles remain open for years, centres of ossification appear late, and the epiphyses remain ununited for long periods. Growth, however, is

always deficient and cretinism is a variety of dwarfism. The facies is characteristic, being pale and pasty, with a thick skin, wrinkled forehead, a broad nose with depressed bridge and big nostrils, and thick lips separated by a protruding enlarged fissured tongue. The hair on the head is dry and scanty, and the eyebrows and eyelashes frequently deficient. The body is characterised by a protruding, pendulous abdomen, with umbilical hernia, supraclavicular pads of fat and some degree of scoliosis and lordosis. The hands are spatulate, with square finger tips, and the limbs lack muscular tone. Deafness is not infrequent, and speech is often impaired. Genital development is always retarded, and ultimate sexual maturity a rarity. As in the case of myxœdema, there is a low basal metabolic rate, subnormal temperature, sensitivity to cold and constipation.

Diagnosis.—To those who have seen the characteristic appearance, the diagnosis of cretinism rarely offers difficulty. In contrast, a Mongol has mongoloid eyes, with epicanthic folds, a good skin and complexion, fine but profuse hair, and a restless, bright manner.

Course and Prognosis.—If untreated, cretins remain semi-idiots and incapable of self-sufficiency, intercurrent infection in childhood or adolescence being a common termination. Infants, treated early, can be made normal, but delayed treatment leads to irreversible changes. Further, mental deterioration may occasionally supervene in later life on approximate normality, which has been maintained by adequate thyroid treatment.

Treatment.—Prophylactic treatment in endemic areas consists of small doses of iodine (see Goitre).

Treatment of the individual patient is specific, namely thyroid. One to 3 grains daily of thyroideum, B.P., or more, may be required, as judged by the general effects and the cardiac rate. If given in infancy or early childhood, an approximation to normal may be attained, but sometimes a harmless, apathetic idiot is merely changed into a mischievous, truculent semi-idiot.

GOITRE

Definition.—A goitre is a pathological enlargement of the thyroid gland, which may be endemic or sporadic, symptomless or associated with hyperthyroidism or hypothyroidism. The contour of the gland may be smooth or nodular.

Ætiology.—Endemic goitre occurs in many regions throughout the world, including certain areas in this country, e.g. Derbyshire and Somerset. In Switzerland, where earlier investigations were undertaken, one factor found to be common to goitrous regions was a deficiency of iodine in the water and soil. This is not always the case in other parts of the world, and goitrogenic agents in an infected water supply have been implicated, although the deleterious effect may be obviated if the iodine content of the water is higher. Vitamin deficiency and a preponderance of calcium over iodine are other possible factors.

The ætiology of sporadic goitre is obscure. Apart from a possible relative iodine deficiency, a familial predisposition is sometimes apparent. The increased demands of the body for thyroxine at puberty may be indicated by a transient physiological thyroid enlargement, but this sometimes persists or increases in size. Endemic goitre is usually obvious in childhood, and its peak incidence is at puberty. This is also true of sporadic goitre, which may however be met with at all ages. The sex incidence of goitre is about equal in childhood, but, after puberty, females are more often affected than males—about 8 to 1.

Pathology.—The smooth diffuse goitres may be divided into the parenchymatous and the colloid, although both histological features are not infrequently present in the same gland. The parenchymatous goitres often show degenerative changes in

the epithelial cells, and areas of fibrosis. The colloid goitres contain low cuboidal epithelium lining vesicles, filled with colloid. Nodular goitres usually contain multiple capsulated adenomas, which may show cystic or hæmorrhagic change. Occasionally there is a single adenoma, which may be of colloid type or of parenchymatous type. In the latter case, it is thought by some to arise from solid masses of embryonic cells that may be seen in normal glands, and for this reason is termed "foetal adenoma."

The above pathological changes occur both in endemic and sporadic goitres.

Symptoms.—When goitre is associated with hyperthyroidism, the symptoms may be those either of Graves's disease or of secondary thyrotoxicosis. When associated with hypothyroidism, the clinical picture is that of cretinism or myxædema.

In all varieties of goitre, including those which are endocrinologically inactive, pressure symptoms may be the major manifestations, especially so in the case of nodular goitres, and when goitres are low down in the neck or behind the sternum (intrathoracic), pressure symptoms may be the only indication apart from that given by radiological examination. Pressure on the trachea may produce difficulty in breathing, irritating cough, alteration in voice and stridor. For mechanical reasons the dyspnoea is worse on lying down, and attacks of dyspnoea with cyanosis may be fatal. The voice is also affected by paralysis of the recurrent laryngeal nerve, this, however, being rarely bilateral. Pressure on veins may produce dilatation of those of the head and neck, with cyanosis, and in the case of intrathoracic goitre, dilated veins may be evident over the chest. Oesophageal pressure and resulting dysphagia are rare, as also are bradycardia due to vagus involvement, and mydriasis and sweating from cervical sympathetic stimulation.

Complications.—Malignant change is said to supervene in 16 per cent. of all goitres, and in 27 per cent. of nodular goitres. It is usually only after some years that malignancy develops, and clinical indications are a rapid increase in size and hardness of the goitre over a period of weeks or months, the development or increase of pressure symptoms, especially dysphagia, and lack of mobility in relation to the adjacent structures, e.g. the trachea. Metastases in the lungs, liver and bones, may unfortunately be the first recognised indication in some patients. The commonest age of onset of malignant changes is from 50 to 70, and such a change is nearly always superimposed on a pre-existing goitre. In cases in which malignant changes supervene, 35 per cent. are correctly diagnosed before operation, 30 per cent. at operation and the remainder only on histological examination.

Diagnosis.—This is usually obvious on inspection. Intrathoracic goitre may be simulated by thymus or mediastinal tumours. Sometimes auricular fibrillation in a middle-aged or elderly person may draw attention to a small pre-existing goitre which has been symptomless for years. Pressure symptoms on the trachea may simulate asthma, perhaps with the complication of bronchitis, and some of these cases are not diagnosed for years.

Course.—A goitre may remain symptomless and innocent throughout life, but at any time symptoms of hyperthyroidism or hypothyroidism may appear.

Treatment.—In Switzerland the addition of iodide to salt, 1 part in 100,000 has enormously reduced the incidence of endemic goitre. In areas of endemic goitre in France, 1 min. of Lugol's iodine daily, has been employed, and in America iodised salt, 1/10,000, both with varying and on the whole satisfactory results. As might have been anticipated, the results are best if iodine has been administered to the mother throughout the pregnancy, but even when first given in childhood the incidence of goitre is considerably reduced. It is to be pointed out that in the case of symptomless endemic goitre, especially of the nodular variety, the use of iodine is not free from the danger of inducing thyrotoxicosis. This is also true in the case of sporadic goitre, although in simple diffuse goitre the risk is probably insignificant.

Some symptomless endemic goitres, however, become hyperactive even without treatment.

The therapeutic, as distinct from the prophylactic, use of iodine in goitre without thyrotoxicosis, endemic or sporadic, is not as beneficial as the iodine-deficiency theory might lead one to expect; and even an initial increase in size may be produced. Thyroid extract to the point of tolerance leads to involution of the goitre in some patients. In others thyroidectomy is indicated for cosmetic reasons or because of pressure symptoms. In children or adolescents thyroidectomy for symptomless goitre is best avoided or deferred as there may be a tendency to recurrence.

DISEASES OF THE PARATHYROID GLANDS

The parathyroids are four in number, and are usually situated symmetrically in the posterior aspect of the thyroid gland. They secrete a hormone, parathormone, which gives protein colour reactions, is soluble in water and 80 per cent. alcohol, but is insoluble in ether or acetone. The chief function of the glands is the regulation of calcium and phosphorus metabolism. Excess of the hormone leads to osteitis fibrosa diffusa, and deficiency to tetany.

HYPERPARATHYROIDISM

Synonyms.—Generalised Osteitis Fibrosa Cystica; Osteitis Fibrosa Diffusa.

Definition.—A disease due to the excessive secretion of parathormone, and manifested clinically by hypercalcaemia, negative calcium balance, muscular atony, weakness and wasting, and decalcification of bones resulting in deformities and fractures.

Ætiology.—The disease, which is rare, is due to a neoplasm or hyperplasia of the parathyroid glands. The latter may be secondary to a pituitary stimulus, but a parathyrotrophic hormone has not been demonstrated in the blood. It affects women twice as frequently as men. The average age incidence is about 40, but it also occurs in childhood and old age.

Pathology.—A circumscribed adenoma of one parathyroid gland is the commonest lesion, the remaining three glands being normal or hypoplastic, but two adenomas have been found at operation. There may, however, be general hypertrophy and hyperplasia of all glands, which is usually obvious to the naked eye, and may even be of extreme degree, e.g. one weighing 5 g. compared with a normal of 60 mg. Such changes are comparable to the hyperplasia, with or without adenomatous formation, in the thyroid gland of thyrotoxicosis. The parathyroid cells are greatly enlarged, and the cytoplasm highly vacuolated. The essential skeletal changes are softening, replacement of bone marrow by fibrous tissue, rarefaction of the cortex, and the presence of numerous osteoclasts and osteoblasts, with osteoclastic giant cells and cyst formation. Deposits of calcium as fine granules may be present in all the viscera, especially the kidneys and lungs. Occasionally hyperplasia of the parathyroid glands is secondary to chronic renal insufficiency.

Symptoms.—These are all the direct or indirect result of excessive calcium mobilisation and excretion. The long bones may be bent and deformed, with perhaps osteoclastic tumours, and in some cases pathological fractures. The vertebræ

are compressed, and not infrequently height is diminished by several inches. Osteoclastic swellings may deform the jaw. The shape of the skull is rarely distorted clinically. The bones and osteoclastomatous swellings are often tender, especially on pressure. The teeth are not decalcified. The muscles show atony, fatigability and atrophy. Gastro-intestinal symptoms are nausea, vomiting, constipation, abdominal pains and cramps. Polyuria and polydipsia are associated with the increased calcium excretion. Urinary symptoms are common. The calcium may be deposited diffusely, giving rise to the presence of chronic nephritis and renal insufficiency, or even multiple renal calculi, the latter consisting chiefly of calcium and phosphorus. Renal colic and pyelocystitis are complications. In some patients the presenting symptoms are those of renal calculus, without any indication of hyperparathyroidism. In clinics where all such cases undergo investigation of calcium metabolism a number (1 to 5 per cent.) have been shown to be due to primary hyperparathyroidism. It is also important to remember that bone changes may be relatively slight and in acute cases undetectable radiographically, although the serum calcium is raised. Acute hyperparathyroidism may present itself as weakness, wasting, drowsiness or semi-coma, nausea or vomiting, and cardiac failure. The condition can be produced experimentally by the injection of parathormone.

Metabolic changes.—The calcium and phosphorus are mobilised from the bones, and excreted in excess in the urine and to a much less extent in the faeces. The serum calcium is usually raised, e.g. 15 mg. per cent. (normal 10 mg.), and the plasma phosphorus is diminished, e.g. 2 mg. per cent. (normal 3.5 mg.). A normal serum calcium does not necessarily exclude the disorder, providing that the serum phosphorus is persistently low, and the calcium balance negative. In the presence of advanced renal disease, however, there may be phosphorus retention and a raised serum phosphorus. The alkaline serum phosphatase is raised, e.g. 24 King-Armstrong units compared with the normal values, 3 to 13 units, and it is a measure of the degree of osteoporosis. Rarely and in the absence of gross osteoporosis the phosphatase may be within normal limits.

Diagnosis.—Radiography shows generalised osteoporosis, with granular mottling in the skull; but an absence of demonstrable radiographic bone changes in itself does not exclude the diagnosis. Multiple calcium deposits, minute and diffusely scattered or large enough to be called calculi, may be shown in skiagrams of the kidneys, and sometimes of the lungs. If estimations of serum calcium, phosphorus and phosphatase are inconclusive, the intake and output of calcium must be measured over a few days to determine if a negative calcium balance is present.

When urinary symptoms are prominent, the underlying primary hyperparathyroidism may be unsuspected in the absence of metabolic investigation. Rarely, hyperparathyroidism of severe degree is secondary to long-standing chronic nephritis, and, in such patients, although the total urinary and faecal calcium excretion is above normal, the serum calcium is normal or slightly less than normal and the phosphorus raised. Differential diagnosis may be very difficult if there is inadequate evidence of the sequence of events.

Gout and arthritis may be simulated, especially if there are tender deposits of calcium in the joints, and some patients are treated for vague rheumatic pains or lumbago. In Paget's osteitis deformans, a disease of middle or old age, there is great deformity of the skull, normal calcium and phosphorus metabolism, but an increased serum phosphatase. Osteomalacia, or adult rickets, is very rare in England and America, and is due to deficient intake of vitamin D or lack of sunshine. The bones are soft and deformed, the plasma phosphatase is raised and the plasma phosphorus is low, but the serum calcium is never above normal and is often below.

Albright has described a syndrome of multiple bone cysts and areas of rarefaction.

segmentally distributed in relation to nerve roots, with corresponding patches of pigmentation. The disorder is found mostly in girls and is associated with sexual precocity. There are no changes in calcium, phosphorus or phosphatase values, the ætiology is uncertain, and parathyroidectomy useless.

Osteoporosis may also be found with prolonged immobility, in old age, in thyrotoxicosis and in eunuchoidism.

Prognosis.—In the absence of surgery, the course of the disease is progressive, and death occurs within a few years. Weakness, wasting and deformities confine the patient to bed. Intercurrent respiratory infection may terminate life, while others die from uræmia or pyelonephritis.

Treatment.—Primary hyperparathyroidism can only be adequately controlled by removal of a parathyroid adenoma or, in the case of hyperplasia, of two or more parathyroid glands. Irradiation is usually ineffective, and a high calcium and phosphorus diet is only mildly beneficial and not without danger in the presence of renal insufficiency. If at operation no adenoma is discovered, the exploration should be continued above and below the thyroid region, behind the œsophagus and into the upper mediastinum, for a parathyroid tumour is sometimes found in such aberrant positions. Even if an adenoma is found in the usual situation, the posterior aspects of the thyroid gland should be completely explored to see if a second adenoma is present, as may be the case. Where there is diffuse hyperplasia of all four glands, no less than three should be removed, and some surgeons remove a portion of the fourth as in subtotal thyroidectomy. Tetany may follow operation for adenoma or hyperplasia, and may appear within a few days of operation, or after a latent period of some weeks. If controlled medically it will tend to disappear after some weeks or months, when the remaining parathyroid tissue has undergone compensatory hyperplasia. It is obviously illogical to give parathormone, which would further decalcify the already softened bones. Following parathyroidectomy, the general symptoms, *e.g.* pains, weakness, anorexia, improve almost at once, but the bones may take several months to become normally calcified. The serum calcium immediately falls to normal or below normal, but the phosphatase tends to remain high for some months, being an indication of osteoblastic activity. The sudden change from high to low serum calcium may cause transitory visual and mental disturbances with apprehension.

HYPOPARATHYROIDISM

Synonym —Parathyroid Tetany

Definition —A disease characterised by neuro-muscular irritability due to a subnormal serum calcium, the latter being the result of deficient secretion of parathormone. All forms of tetany are due to subnormal concentrations of ionised calcium in the serum but this is not necessarily the result of parathyroid hypofunction.

Ætiology —Idiopathic hypoparathyroidism occurs sporadically, and may do so at any age, but it is comparatively rare, or perhaps not sufficiently well recognised. A familial incidence of hypoparathyroidism has been recorded, including examples of onset in infancy. The majority of cases follow thyroidectomy, and although this may be due to removal of parathyroid tissue, it is more often due to interference with blood supply. Hypoparathyroidism may also follow the removal of a parathyroid tumour, or two or more hyperplastic glands in *osteitis fibrosa diffusa*. Parathyroidectomised animals show decreased urinary phosphorus excretion and rise in plasma phosphorus before changes in calcium metabolism are apparent. Later, however, there is a fall in serum calcium in spite of a positive calcium balance, and the animal dies in tetanic convulsions. Parathormone injections will prevent or correct the changes in phosphorus and calcium metabolism. Tetany also occurs in conditions

other than hypoparathyroidism if the concentration of calcium in the blood falls below normal

Thus in rickets, osteomalacia and steatorrhœa there is a deficient absorption and utilisation of calcium. The increased demands for calcium in pregnancy and lactation may render a latent tetany manifest. Tetany may be found in alkalosis, the total serum calcium being normal, but the ionised fraction below normal, alkalosis may result from excessive vomiting, hysterical hyperpnœa, or treatment with alkalis.

Pathology—In idiopathic hypoparathyroidism, the parathyroid glands may be atrophic, or replaced by fibrous or fatty tissue with round-celled infiltration, in post parathyroidectomy tetany, too much parathyroid tissue has been removed or the residual parathyroid tissue has not yet had time to undergo compensatory hypertrophy.

Symptoms—Following thyroidectomy and parathyroidectomy, symptoms may appear within the first 48 hours or may be delayed for weeks or months. There is often irritability, nervousness and apprehension in addition to weakness. Paræsthesiæ and muscular cramps and stiffness are common in the hands, especially on the ulnar aspect, but may also occur in the feet. They are followed or accompanied by muscular contractions of the hands and feet, giving the classical picture of carpo-pedal spasm. The "obstetric hand" is produced by flexion at the metacarpo-phalangeal joints, extension at the interphalangeal joints and adduction of the thumb. Spasm of the laryngeal muscles may produce hoarseness and stridor, and, if the bronchial muscles are also involved, respiratory distress and cyanosis result, sometimes with fatal convulsions or coma. A form of chronic pseudo-asthma associated with bronchial spasm is also a manifestation of hypoparathyroidism. Tetanic muscular spasms are not infrequently painful and may cause the patient to cry out in distress.

In long standing hypoparathyroidism, ectodermal defects become apparent, with brittleness and ridging of the nails, loss of hair and transverse ridging of the decalcified teeth. Blurring of vision, perhaps leading to blindness, is due to opacity of the lens, minor degrees of which may be detected by means of a slit lamp even in the absence of ocular symptoms. Muscular spasm may involve ocular muscles.

Various cerebral and mental disturbances may be due to chronic hypoparathyroidism. They include changes in character, mental instability, anxiety, depression, impairment of memory and intellect, and more rarely hallucinations, confusion, manic depressive states, paranoia and dementia. Major epilepsy and petit mal are rare. Migraine may be a presenting feature. Skull radiographs may show calcium deposits in the basal ganglia of the brain.

Gastric spasm may cause pain and vomiting, and spasm of the bile passages simulate cholelithiasis, especially if associated with transitory jaundice. Laparotomy has been performed for symptoms suggesting appendicitis or perforated peptic ulcer, and ileal spasm may produce fatal ileus. Cardiac pain or a sense of constriction with palpitation may occur, the electrocardiogram shows a characteristic prolongation of the Q-T interval.

Diagnosis—Although in most cases diagnosis is obvious, mild degrees of hypoparathyroidism with general irritability, weakness and paræsthesiæ and only slight ectodermal deficiencies, may not be suspected. The following classical signs are of diagnostic value. Chvostek's sign is the production of contraction of facial muscles by tapping the facial nerve below the zygoma, Trousseau's sign is the production of carpal spasm by a sphygmomanometer band on the arm at a pressure just above systolic, Erb's sign is an exaggerated muscular contraction in response to minimal electrical stimuli. The failure to elicit one or more of these signs does not exclude the diagnosis. Biochemical evidence is often conclusive. In hypoparathyroidism the serum calcium is always below the normal value of 10 mg per 100 ml (e.g. 6 mg)

and the plasma phosphorus is above the normal 3.5 mg (*e.g.* 7 mg), there is decreased urinary excretion of phosphorus and calcium. In a doubtful case, a high phosphorus diet will depress the serum calcium and produce symptoms, this does not occur with normal parathyroids. It is interesting to note, however, that in cattle there is a form of tetany, which is the result of excessive phosphorus in the diet.

Treatment.—The logical treatment of hypoparathyroidism is solution of parathyroid, USP (parathormone), which acts by increasing the excretion of urinary phosphorus and mobilising calcium from the bones thus raising the serum calcium. This form of treatment, however, has several disadvantages. It is useless in acute tetany because subcutaneous or intramuscular injections may take 8 or more hours to be effective and are variable in their effect. While intravenous injection is quicker it takes a few hours to act and, moreover, by this route there is a danger of a protein shock-like reaction in some patients. Four-hourly injections of 1 ml of parathyroid solution (20 units) intramuscularly or subcutaneously may, however, be effective after the initial latent period. Rarely, overdosage of injected parathyroid hormone results in nausea, vomiting, diarrhoea, failing circulation, dehydration, increased viscosity of blood, coma and death. With controlled serum calcium estimations, however, overdosage is a rarity and 40 units daily may sometimes not be adequate to control the disorder. Even when solution of parathyroid is effective at first, a refractory state sets in after some weeks. The latter is probably not due to the production of anti-hormone substances in the blood, as in the case of other hormones, but to local tissue immunity since an intravenous injection of solution of parathyroid may still be effective. Nevertheless, this refractory state renders prolonged therapy with solution of parathyroid impracticable.

The immediate treatment of acute tetany is the intravenous or intramuscular injection of calcium gluconate, 20 ml of a 10 per cent solution, the effect being rapid and dramatic, but only lasting some hours. The injections must be administered slowly, but a little leakage from a vein has not the local deleterious effects of calcium chloride. It is necessary to follow this emergency injection by large doses of calcium gluconate or lactate by mouth, *e.g.* 12 g daily in divided dosage. Calcium chloride is less pleasant to take, and in practice the theoretical value of the resulting acidosis is hardly significant. This is perhaps less true of the addition of 3 g of ammonium chloride, daily, in 1 g capsules. In many cases calcium gluconate or lactate by mouth is sufficient to control the tetany. If not, vitamin D should also be given. It acts by increasing calcium absorption from the intestine and secondarily by increasing phosphorus excretion in the urine. The dosage of vitamin D, or calciferol, should be high, 50,000 to 200,000 units daily may be required. In severe cases these measures may still be ineffective, and then a derivative of irradiated ergosterol, dihydrotachysterol (A.T. 10) is of great value. It is not anturachitic, probably because it also causes considerable excretion of phosphorus from the urine, but it produces a great increase in calcium absorption from the intestine and a rise of serum calcium to normal or above normal. Like vitamin D it is of no use in emergency, the effect not being produced for some 24 to 48 hours. It is, however, cumulative in action, and the dosage should be controlled by periodic serum calcium estimations if hypercalcaemia is to be avoided. The urinary test of Sulkowitch is a useful indication of dosage. The reagent consists of oxalic acid and ammonium oxalate in glacial acetic acid, and equal amounts of urine and reagent are mixed. If no precipitate occurs, the serum calcium is probably below 7.5 mg per 100 ml, as the renal threshold for calcium varies between 7.5 and 9, if there is a fine white cloud, the serum calcium is probably normal, about 10, if the precipitate is milky, the serum calcium is abnormally high. Using this technique Albright gives 3 ml of dihydrotachysterol a day by mouth until calcium appears in the urine, after which 1 ml, 3 to 5 times a week is usually adequate. Dihydrotachysterol is prepared in

an oily solvent containing 5 mg of the drug per ml, and is administered by mouth

Diet in hypoparathyroidism is a matter of controversy. High calcium diets (milk, cheese, egg yolk) have the serious disadvantage of also being high phosphorus diets. It is better, therefore, to prescribe a normal diet, or preferably a low phosphorus diet, and to supply the extra calcium as calcium lactate or gluconate. A diet containing no milk, cheese, egg-yolk, meat or nuts, but a liberal amount of fruit, vegetables, carbohydrates, fats and white of egg contains little phosphorus.

DISEASES OF THE SUPRARENAL GLANDS

The suprarenal gland consists of cortex and medulla. The cortex is of mesoblastic origin, while the medulla is ectodermal. The cortex is composed of lipid-containing epithelial cells, arranged from without inwards in three zones, zona glomerulosa, zona fasciculata and zona reticularis. The inner portion of the latter contains brightly staining granules (pigment zone). The medullary cells have an affinity for chromic acid stains, and are termed chromaffin cells. The adrenal glands are supplied by sympathetic nerves from the splanchnic and celiac ganglia, but they are cholinergic.

The medulla is not essential to life. It secretes adrenaline and nor-adrenaline and its function will be discussed under the heading Phæochromocytoma. It is anatomically separate from the cortex in fishes but a functional relationship exists in that adrenaline can stimulate the secretion of adrenocorticotrophic hormone by the pituitary. This probably occurs only in emergencies.

The adrenal cortex is essential to life, and bilateral adrenalectomy results in death within 7 to 10 days. The steroids secreted by the cortex may be divided into three main groups, the glucocorticoids, the mineralocorticoids and the sex hormones.

(1) The glucocorticoids (11-oxysteroids) are diabetogenic and catabolise protein. Gluconeogenesis results from the excessive breakdown of protein (or failure of anabolism), the glucose being transformed into hepatic glycogen and also into fat. There is also a decreased rate of utilisation of glucose. Protein breakdown is also reflected in creatinuria and increased excretion of uric acid. There is a shift of fat from the extremities to the face and trunk and the liver also contains an excess of fat. Ketosis may result. Other effects are involution of lymphoid tissue, decrease of blood lymphocytes and disappearance of eosinophil cells.

Kendall of the Mayo Clinic and Reichstein of Zurich identified many of these corticosteroids. Kendall gave them alphabetic names, e.g. Compound A (11-dehydrocorticosterone), Compound B (corticosterone), Compound E (11-dehydro-17-hydroxycorticosterone) and Compound F (17-hydroxycorticosterone). Compound F appears to be the main constituent of the adrenal venous blood of dog and man, and Compound B is present in lesser degree. Compounds A and E are found only in traces. Compound F is also called cortisone and is very similar in chemistry and action to Compound F. Compound F has been isolated in large quantities from the urine in Cushing's disease with associated severe diabetes. Compound E has been synthesised from bile and from stigmasterol, a steroid found in the soya bean. Compound A and, less so, Compound B are very potent in producing a deposition of fat in mice.

(2) Mineral corticoids—corticosteroids with influence on electrolytes and water balance. After the glucocorticosteroids (Group 1) have been crystallised from an extract of adrenal cortex, there remains an amorphous residual fraction which is

highly potent in maintaining the electrolyte and water balance in adrenalectomised animals. This fraction is far more potent, weight for weight, than is 17-hydroxy-11-desoxycortone (deoxycortone), a substance synthesised by Reichstein in 1938 and used therapeutically in Addison's disease, but which is probably not a natural constituent of the adrenal gland. Deoxycortone has largely been used for its influence on water and mineral metabolism. It causes retention of sodium and an excretion of potassium, with a lowering of tissue and plasma potassium, and thus it is capable of reversing the changes found in the adrenalectomised animal. Chloride tends to behave as sodium, although not invariably, and water tends to be retained with the sodium chloride. Fluid balance is a complicated subject and it requires the consideration not only of total retention or loss, but of the distribution of fluid between tissues and plasma and between intracellular and extracellular fluid.

The glucocorticoids have some action on water metabolism, which varies with circumstances, causing retention during overdosage, but producing diuresis in Simmonds's and Addison's disease. They also cause excretion of potassium and retention of sodium. By chromatographic studies and using the Na/K ratio in the urine of adrenalectomised mice, after injecting Na and K isotopes, J. F. Tait and S. A. Simpson have separated a mineral-corticoid fraction in beef adrenal extracts of far greater potency than that of deoxycortone or of any previously separated adrenal glucocorticoid. Its relationship to the amorphous fraction is unknown.

(3) *Sex hormones*.—The urine of castrated men and women contains androgens derived from the adrenal cortex. In normal men two-thirds of the urinary androgens come from the adrenals and only one-third from the testes. The whole of the urinary androgens in females come from the adrenals. A number of androgens have been isolated from the adrenals, the chief being androsterone. Urinary androgens may be assayed by a chemical colour reaction and are measured as 17-ketosteroids, the latter possessing a ketone group at the 17th carbon atom. 17-ketosteroids are divided into alpha and beta ketosteroids according to the position of the 3-hydroxy group. The alpha group includes androsterone and the beta group includes dehydroisoandrosterone, which is found in large quantities in the urine of patients with adrenal neoplasms. Although it is uncertain whether, or to what extent, the adrenals secrete oestrogens and progesterone in normal men and women, there is no doubt that such hormones are secreted, often in large quantities, by adrenal tumours, especially in males.

ADDISON'S DISEASE

Synonyms.—Hypocorticalism; Adrenal Cortical Insufficiency.

Definition.—A disease due to destruction and hypofunction of the adrenal cortex, and manifested by pigmentation, weakness, myasthenia, anorexia, loss of weight and hypotension. It was first described by Thomas Addison in 1849.

Ætiology.—The disease is found among all races, and in all climates. Males and females are affected about equally. It is commonest between the ages of 20 and 40, and rare in childhood and old age. Tuberculosis is the most common cause. Severe infections, primary or secondary carcinoma, hæmochromatosis, arsenic poisoning and hæmorrhage are rarely responsible.

Pathology.—In tuberculosis both the medulla and cortex are usually destroyed, except for small islets of surviving tissue. The gland is replaced by caseous tissue, with areas of fibrosis, giant cells and lymphocytes. Other organs may also be affected, but pulmonary tuberculosis is rare. A history of gland or bone tuberculosis in childhood or in other members of the family is not uncommon. The next most common cause is atrophy of the cortex, of unknown origin, the medulla being scarcely affected. The cortex is almost entirely replaced by connective tissue and dilated capillaries,

with infiltration of lymphocytes, plasma cells and leucocytes. The picture is more like a toxic necrosis than a simple atrophy. Rare lesions are syphilis, amyloid disease, hæmorrhage, infarction, hæmochromatosis and malignant growth. The last may apparently produce the disease even when it involves the sympathetic nerve supply only, sparing the actual glands.

Symptoms—Weakness, loss of appetite, loss of strength and pigmentation are the usual presenting features.

The onset is often gradual. Occasionally the patient is not seen until a grave crisis has developed. This is especially so when pigmentation is not a conspicuous feature. Usually the patient complains of feeling vaguely unwell. He (or she) may be languid, lacking in strength and easily tired. Appetite is poor, and there may be a special aversion to fatty foods. In more severe insufficiency, nausea and even vomiting are distressing features, while abdominal pain, rarely sufficiently severe to simulate an acute abdomen, is occasionally present. Abdominal pain is rare during the less acute phases but there may be aching in the loin or referred to the shoulder due to irritation of the diaphragm. Constipation is common, but there may be intermittent attacks of diarrhoea, either spontaneous or following purgatives, and these may initiate a crisis. Hiccups, yawning and conjunctivitis suggest deterioration in the patient's condition. There is progressive loss of weight, myasthenia and general weakness.

Generalised pigmentation, due to the deposition of melanin in the mucous membranes as well as the skin, is a classical sign of the disease. In the skin it is deposited in the basal layer of the epidermis, and in amounts greater than normal. Brown patches and streaks may be found on the inner aspects of the cheeks, the soft palate and posterior portion of the hard palate, the sides of the tongue, the gums and the mucous surface of the lips, especially at the corners of the mouth. The distribution of skin pigmentation is partly determined by exposure to light and irritation. Thus, it is most marked on the face and neck, dorsum of the hands and forearms, waist line, garter area, axillary folds and vulva, and in areas of skin overlying bony prominences, e.g. knuckles, ischial tuberosities and ankles. The palms show no evidence of increased pigmentation, except in the interphalangeal creases. Occasionally there are scattered pigmented spots on the face and body and the nails may also be pigmented and striated. Although pigmentation is a classical sign of Addison's disease, it may be inconspicuous or even absent in fair-skinned people, or when the onset is acute. There may be associated leucoderma.

There is considerable variation in the degree of interference with sex function. In some there is none, while in others there is amenorrhœa or impotence. Hypogonadism is certainly not an essential feature. Many patients feel the cold badly, especially in more severe insufficiency. The body temperature may be normal or subnormal, with perhaps intermittent pyrexia, and the basal metabolism is rarely appreciably lowered, except in crisis. The systolic blood pressure is characteristically below 100 mm of mercury, but this does not necessarily give rise to symptoms, and a normal blood pressure may persist for some time. Although in some patients the fasting blood sugar and carbohydrate tolerance curves may be normal, in others there is a persistent or intermittent hypoglycæmia which may even be fatal if unrelieved by glucose or adrenaline. There is an increased sensitivity to infections, shock, surgical trauma, hæmorrhage and drugs.

In crisis, the patient is collapsed and cold. Stupor and apathy are characteristic but there is also irritability, intractability and restlessness. The patient tends to curl up deep in the bed beneath the covering, and to resent interference. The pulse is rapid and of poor volume, and the blood pressure tends to fall acutely. Nausea, vomiting and diarrhoea may be persistent, thus adding to the dehydration that has resulted from the increased loss of salt and water through the kidneys. The veins are collapsed and the blood viscous. Ultimately urine becomes scanty in

amount, and terminally may contain casts and albumin. Pigmentation tends to increase in the more severe degrees of insufficiency, and crops of discrete deeply pigmented spots may appear. The blood sugar falls during crises, the serum sodium, plasma chloride and alkali reserve become even lower than previously and the serum potassium concentration higher.

Complications.—Addison's disease may rarely be complicated by thyrotoxicosis, myxœdema or diabetes. Other tuberculous lesions or intermittent infections, such as pneumonia, are not uncommon.

Diagnosis.—Clinically, this depends upon the classical features of pigmentation, weakness, wasting, anorexia and hypotension. Cutaneous pigmentation may also be found in other conditions, including hæmochromatosis, Hodgkin's disease, exophthalmic goitre, Cushing's syndrome, pernicious anæmia, arsenical poisoning, malignant cachexia, ochronosis, argyria, parasitic irritation, leucoderma and pregnancy. In Simmonds's cachexia, a condition which has many features in common with Addison's disease, pigmentation is usually absent and is hardly ever diffuse, or marked. It is important to note that pigmentation of the mucous membranes is practically pathognomonic of Addison's disease. It is said by some to occur very rarely with pernicious anæmia, malignant cachexia and arsenical poisoning. Of the first, I wish to record that two authorities on pernicious anæmia have never met with pigmentation of the mucous membranes in this disease; of the second and third I would presume infiltration of the adrenal glands by metastases or by arsenic. In people of the negro race, or in those with an antecedent negroid admixture, pigmentation of the mucous membranes may occur normally. It may also occur in intestinal polyposis.

Laboratory aid should more often be sought to exclude Addison's disease than to confirm a diagnosis, confidently made on clinical grounds. One should be very hesitant about discarding such a diagnosis because of normal or atypical chemical findings. Normal values are: serum sodium, 315 to 350 mg. per cent. (140 to 150 meq. per litre), serum potassium, 18 to 21 mg. per cent. (4.6 to 5.0 meq. per litre), plasma chloride as NaCl, 560 to 630 mg. per cent. (95 to 110 meq. per litre) and plasma bicarbonate, 53 to 77 vols. CO₂ per 100 ml. (25 to 35 meq. per litre as H₂CO₃). In severe adrenal insufficiency the blood sodium and chloride are low, the potassium raised and the alkali reserve low. Blood urea is raised in severe phases partly due to hæmoconcentration associated with electrolyte and water balance and partly due to poor renal function. Hæmoglobin and hæmatocrit values are also raised as an expression of hæmoconcentration, and when anæmia is present a low hæmoglobin may not be revealed until hæmoconcentration has been corrected by treatment. There may be relative lymphocytosis, eosinophilia and an increased sedimentation rate.

The Kepler test is a measure of the rate of the elimination of water and to a lesser degree of chloride and urea. The night urine is measured and in the morning a litre of water (20 ml. per kg. body weight) is drunk and the urine collected hourly or 4 hours. If none of these hourly specimens is greater than the total night urine the diagnosis of Addison's disease is confirmed (Part I). Further confirmation (Part II) is sought by withdrawing venous blood and calculating Factor A—

$$A = \frac{\text{Urine Urea}}{\text{Plasma Urea}} \times \frac{\text{Plasma Chloride}}{\text{Urine Chloride}} \times \frac{\text{Day Urine}}{\text{Night Urine}}$$

Urea and chloride are expressed as mg. per cent. Day urine represents the largest volume in 1 hour; night urine the total night urine (10 p.m. to 7 a.m.). If A is greater than 30, the diagnosis of Addison's disease is not supported, the usual value for adrenal insufficiency being less than 15. The test is only slightly modified by deoxycortone but is reversed to normality by cortisone which produces normal diuresis.

The carbohydrate tolerance curve is not necessarily abnormal but the physiological hypoglycaemia at the end of the test period may be accentuated. The insulin sensitivity test is midway between normality and that of Simmonds's disease. The urinary 17 ketosteroids are very low in the female and reduced in the male. The 11-oxysteroids tend to be low but are a less reliable index.

The response to pituitary corticotrophin is the basis of a test devised by Thorn. Corticotrophin (ACTH) is injected in doses of 25 mg at intervals of 6 hours for 48 hours. The urinary 17 ketosteroids are measured for 24 hours before the test and during the last 24 hours of the test. In Addison's disease there is no appreciable increase in 17-ketosteroid excretion as there is little or no healthy adrenal cortex left to respond. Neither is there a decrease in eosinophil cells in the blood, either after 4 hours, or after 48 hours, in contrast to a normal response of over 50 per cent decrease in 4 hours and almost complete disappearance in 48 hours.

When tuberculous lesions of the adrenal glands have become calcified, radiology may be of diagnostic help by revealing calcareous shadows in the costo-vertebral angle.

Prognosis—In the absence of treatment, there is progressive deterioration and death within months or years. With adequate substitution therapy, life may be prolonged, but the sensitivity to intercurrent infection is always a danger. Very rarely there is a spontaneous recovery of adrenal function sufficient to permit the cessation of substitution therapy.

Treatment—Until cortisone became available, treatment consisted of deoxycortone acetate (DOCA) given by intramuscular daily injections or by subcutaneous implantation, in either case supplemented by salt by mouth. Salt alone was adequate for mild cases. Patients, however, were very liable to intercurrent infection and/or hypoglycaemic attacks and these caused death in some 50 per cent of patients within 10 years. Cortisone should now be considered an essential part of treatment for the majority of cases. It makes the patient less liable to infection and hypoglycaemia, and increases appetite, strength and well being, abolishing at the same time the depression, apathy and negativism which characterise the behaviour pattern. In large doses, cortisone may reactivate tuberculous lesions, but in Addison's disease, with doses less than the physiological requirement of 50 mg daily, this does not appear to be the case. For safety the basic dose should be 25 mg daily, given as half a tablet by mouth twice daily, and the maximum daily dosage should not exceed 37.5 mg.

In so far as cortisone has some action on electrolyte and water balance, mild cases will not require supplementary therapy with deoxycortone, but most patients will require extra salt in the form of capsules of 1 g three times a day. Others may require as much as 12 g of salt a day and in the more severe cases it will be necessary to give deoxycortone as well. This can be done in several ways—

- (1) By subcutaneous daily injections in oil, the average dose being 2 to 5 mg
- (2) By intramuscular injection of a suspension of trimethyl acetate deoxycortone Crystules the average dose being 50 to 100 mg and the effect lasting some 4 weeks
- (3) By implantation of tablets into the subcutaneous fat of the lower abdomen or upper thigh, the average dose being between 200 and 400 mg, and the effect lasting 6 months. This dose is calculated on the basis of one 100 mg tablet for each 1 mg of deoxycortone acetate, in oil, required by daily injection for maintenance.

Where deoxycortone is used, it may be unnecessary to take extra salt except on occasions, e.g. when long acting Crystules or implants are almost completely absorbed. Where cortisone is not available, deoxycortone, with or without salt, is reasonably effective although it is qualitatively an incomplete form of therapy. In so far as deoxycortone, in large doses, can produce excessive elimination of potassium, with a fatal outcome, initial therapy should be with smaller doses and the danger of over dosage should always be borne in mind. In this connection it should also be remem-

bered that tissue potassium may be lowered before the blood shows any change. Apart from general malaise, nausea and rapid pulse, a cough with frothy sputum and flaccid muscular paresis are features of deoxycortone over-dosage. The physical signs include hypertension, œdema and crepitations at the bases of the lungs, but the blood pressure may fall with cardiac failure.

The treatment of crisis is much the same as the treatment of chronic adrenal insufficiency described above, except that it is more intensive. Cortisone is essential, particularly in the presence of hypoglycæmia. Cortisone by mouth acts within an hour and unless the patient is comatose this is the best route of administration. Intramuscular or subcutaneous cortisone takes several hours to become effective but the effect lasts for some 24 hours. In the presence of complete collapse, with or without hypoglycæmia, the intravenous administration of glucose and saline is called for. In crisis the veins are collapsed and difficult to enter and it may be necessary to expose a vein by incision. As previously stated, active treatment may transform a state of adrenal insufficiency to one of over-dosage so that if a patient recovers from the initial crisis and then appears to relapse in the face of active treatment, the possibility of over-dosage must be considered.

ACUTE SUPRARENAL DEFICIENCY

Apart from Addison's disease, there is some clinical and pathological evidence that acute adrenal insufficiency occurs with certain infections, such as meningococcal septicæmia, diphtheria, typhoid fever and pneumonia. At necropsy, the suprarenals show congestion, œdema, hæmorrhage and necrosis. Such lesions may also be found in fatal eclampsia.

The onset is sudden. Malaise, restlessness, headache, vomiting, fever, chills, sweating, abdominal pain, cyanosis, scattered petechiæ and stupor or coma, are the main features. When the underlying lesion is acute bilateral suprarenal hæmorrhage, the term Waterhouse-Friderichsen syndrome has been applied to the clinical condition. This syndrome is usually associated with meningococcal septicæmia, and is more common in infants than in adults.

Acute suprarenal insufficiency may also complicate surgical shock and severe burns, the biochemical changes in the blood resembling those found in the more severe phases of Addison's disease.

Diagnosis.—The diagnosis of acute suprarenal insufficiency as a complication of infections, surgical shock and burns, is often a matter of assumption, based on experimental evidence. That of the Waterhouse-Friderichsen syndrome is only occasionally made in life, but is suggested by early cyanosis, collapse and fall of blood pressure in a patient suffering from a meningococcal infection. Subacute adrenal insufficiency may develop with any severe infection but the diagnosis is not easily substantiated.

Treatment.—Treatment is similar to that described for the crises of Addison's disease.

ADRENO-GENITAL SYNDROME

Synonym.—Virilism.

Definition.—A combination of hirsutism with amenorrhœa, or oligomenorrhœa. There are two clinical types, adipose or muscular.

Ætiology.—The immediate cause is hypersecretion of androgenic hormone by the adrenal cortex, and this is the only type of hypersecretion in the muscular variety of the disease. In the adipose variety there is also hypersecretion of glucocorticoids,

and it is not always possible to differentiate between this adipose type and incomplete forms of Cushing's syndrome, particularly when the latter is associated with coincident androgenic features. The excess of androgen inhibits pituitary gonadotrophic function. There appears to be a greater incidence among Jewish, Celtic and Mediterranean people. There is, however, no sharp dividing line between milder cases of the disorder and accepted normality.

Pathology—The lesion is an adenoma, a carcinoma or a bilateral hypertrophy of the adrenal cortex. The cells have an affinity for the Ponceau fuchsin stain, and are thought to arise from the inner androgenic zone of the cortex. There may be a general lymphoid hyperplasia, and a large thymus. The ovaries tend to be atrophic and cystic.

Symptoms—The changes usually begin at or soon after puberty, but may not become prominent until the late teens, or sometimes in the twenties, or later. The essential feature is an excessive growth of hair on the side of the face, the upper lip and chin, the forearms, thighs, buttocks and legs and on the trunk. The last may be only slightly affected in the form of a linear growth of hair extending from the usual feminine horizontal upper limit of pubic hair upwards along the linea alba to the umbilicus, or the hair may cover the abdomen and chest, and tufts of hair surround the nipples. Menstruation may cease altogether, or there may be oligomenorrhea. The uterus may become small or may fail to develop, but more usually there is no gross change in its size. The clitoris may be normal or appreciably enlarged sometimes resembling a small penis. The breasts may be atrophic or undeveloped but when there is adiposity this feature is obscured. The adipose type is more common. Fat is deposited on the face, neck, breasts, abdomen, pubes and thighs, leaving the legs and forearms thin. In the muscular type the normal feminine contours fail to develop, or may be lost through disappearance of adipose tissue and the muscles are strongly developed with broad shoulders and narrow hips as in the male.

Complications—There may be some degree of pigmentation around the eyes. Psycho-neurosis and psychosis, with loss of heterosexual desire and homosexual tendencies may be complications. A complete feminine mentality, however, may be associated with virilism, giving rise to a fear of sex conversion and of feminine inadequacy.

Diagnosis—A combination of hirsutism and amenorrhoea makes the diagnosis probable. A tumour should be suspected if the disease has started after the twenties in a person hitherto quite normal, and in no case can it be excluded without investigation. Appreciable enlargement of the clitoris is common with a tumour, or with purely androgenic hyperplasia. An intravenous pyelogram may demonstrate a neoplasm. A more certain method, though not without danger, is perirenal insufflation of 450 ml of air, the neoplasm being shown surrounded by air in the skiagram. Ovarian tumours (arrhenoblastoma) may produce virilism, they are not always palpable on vaginal examination, and may be revealed by laparotomy.

Androgenic hormone is usually secreted in excess in virilism. If the quantity of 17 ketosteroids excreted in 24 hours is greater than 30 mg (normal 5 to 12 mg) an adrenal tumour should be suspected, although higher values than this may be found with simple hyperplasia. Occasionally enormously high values, 180 mg, may be found with an adrenal tumour. If after removal of an adrenal tumour, the values for 17 ketosteroids fall and then rise again to high levels, malignant metastases or a tumour of the opposite adrenal gland should be suspected. The presence of dehydroisandrosterone in large quantities in the urine indicates neoplasm rather than hyperplasia. Virilism complicating acromegaly is due to hypertrophy of the adrenal cortex. It may also be a feature of gigantism or may be present in big boned but otherwise normal individuals. These facts justify the concept of a pituitary type of virilism due to an excessive pituitary adrenocorticotrophic stimulation of androgenic type.

Diabetes is not a feature of the adrenogenital syndrome, but in the adipose type

carbohydrate tolerance may be impaired. This is probably due to excessive secretion of glucocorticoids. Values for blood electrolytes are usually normal. Idiopathic or genetic hirsutism is attributed to hypersensitivity of the hair follicles to a normal stimulus and adrenal androgens are assumed not to be secreted in excess. Such patients, however, may later develop oligomenorrhœa or amenorrhœa and it is difficult to make a clear cut division. Further, moderate cases of adreno-genital syndrome may have values for urinary 17-ketosteroids which are within the normal range, but this does not necessarily mean that the androgens secreted by the adrenal cortex are not in excess of normal.

Prognosis—In the case of hyperplasia, the condition may be stationary or only slightly progressive for many years. Sterility is the rule, but this is not invariable. The successful removal of an innocent tumour may produce a reversion to normal. Carcinoma of the adrenal cortex is very malignant, and metastases or recurrences are common.

Treatment—A tumour should obviously be removed surgically. The opposite adrenal is rarely atrophied in the case of an adrenal tumour that is entirely, or predominantly, androgenic in character. Nevertheless, for safety, cortisone should be given before and for a short time after operation, as in the case of adrenal glucocorticoid secreting tumours.

The commonest cause of the adreno genital syndrome, however, is bilateral hyperplasia of the adrenal cortex. Unilateral adrenalectomy often produces a return of menstruation but rarely affects the hirsutism to any appreciable degree and certainly does not affect adiposity. Experience with bilateral subtotal adrenalectomy for this condition is still limited and such a procedure should not be advocated except for very severe cases. One cannot guarantee that the hirsutism will necessarily disappear, because, unfortunately, such disappearance of hirsutism does not always follow even the removal of an adrenal tumour.

Cortisone in large doses, e.g. 50 to 100 mg daily produces an amelioration of hirsutism and development of the breasts and a return of menstruation. It also causes the disappearance of acne. These ameliorating effects are associated with a reduction of the urinary excretion of 17 ketosteroids to normal and such assays can be used to determine the effective dose of cortisone. The effects only last as long as the cortisone is continued, however, and cortisone given in large doses over long periods has its own disadvantages. Larger doses of oestrogens have been advocated but in the writer's experience their effect is little or nil. Where an ovarian androgenic tumour is present it should be removed. As to local methods of removing hairs, electrolysis has a definite but limited value, but irradiation is contraindicated because of the danger of scars and even of carcinoma. Shaving is acceptable to some women and has some advantages.

FEMINISATION

This condition is rare compared with virilism. It is due to a tumour of the adrenal cortex in the male, usually malignant. There is a loss of libido and sexual potency, with a general increase in fat deposition and a hyperplasia of the glandular tissue of the breasts. The latter become enlarged, the nipples pigmented and the superficial veins dilated. There may even be some secretion, which can be expressed from the nipples as in incipient lactation. The patient usually dies from malignant metastases, but in one case successful removal of the tumour led to a return to normal. The testes on section show atrophy. It is interesting to note, and of diagnostic significance, that whereas adrenal cortical tumours, producing virilism in women, secrete very large quantities of androgens, similar tumours (not capable of histological differentiation) producing feminisation in man, secrete enormous quantities of oestrogens, e.g. 4000 mouse units in 24 hours. There is a return to normal values, e.g.

200 mouse units, on removal of the tumour, and increasing values if malignant recurrence or metastases follow

HERMAPHRODITISM

True hermaphrodites have both male and female gonads, namely, one testis and one ovary, or an ovo testis in one organ. They are extremely rare, and it is probable that up to the present time not more than 30 cases have been described. Hermaphroditism is normal for some of the lower species, *e.g.* the worm, and is not a rarity among pigs and goats. In the hen, the right gonad is rudimentary, but if the left ovary is removed the right gonad becomes a testis and the hen grows a comb. Further, any remnant of the left ovary that is left behind may grow into testicular tissue, since the medulla of the ovary is the homologue of the testis. The change of sex in the hen may be so complete that the mother of chicks may become the father of chicks. In man the external genitals may give no indication of the internal genitals. Young, in 1933, described what he regarded as the twelfth case of true hermaphroditism on record. A young "male", tall and athletic, with penis and scrotum, and masculine hair, came to operation for undescended left "testicle". On opening the left inguinal canal, it was found to contain a uterus, Fallopian tube and functional ovary. A portion of the right gonad in the scrotum was excised, and a section showed normal testicular tissue.

True hermaphroditism is genetically determined and is not primarily due to hormonal imbalance. This is well illustrated by the bullfinch, which may have a testis on the right and an ovary on the left, with masculine plumage on the right half of the body and feminine plumage on the left half. Huggins, Cohen and Harden reported another type of true hermaphroditism in which the patient was brought up and behaved as a woman, one gonad was a testis and the other an ovo testis. Both were removed from the inguinal canal and examined histologically. The patient was athletic and slightly hirsute, had a normal vagina and uterus, and began to menstruate at the age of 14, at which time the clitoris became grossly enlarged and assumed the size of a small penis.

PSEUDO-HERMAPHRODITISM

Synonym —Inter sex

Definition.—Pseudo hermaphroditism is a condition in which there is only one type of gonad, testis or ovary, but in which the external genitals are a mixed representation of male and female characteristics, or characteristic of the opposite sex to the gonads. Strictly the term should be applied only to those cases in which the condition is present from birth, and not to those instances of virilism or feminisation which appear in later life. It is also not intended to include under this heading sexual precocity in the female due to an adrenal tumour and associated with hirsutism. Classification according to the type of gonad is the simplest, *i.e.* testicular pseudo-hermaphroditism and ovarian pseudo-hermaphroditism.

Ætiology and Pathology—Pseudo hermaphroditism is sometimes due to genetic factors unrelated to hormones, when, for example, there is failure of development of genital structures or persistence of rudimentary features. Of more classical importance are the types which are due to excessive secretion of hormones, commencing in foetal life. Experimentally the embryo can be influenced by the injection into the mother of androgens or of oestrogens.

Ovarian pseudo-hermaphroditism (where the gonad is the ovary) is due to excessive secretion of adrenal androgens, both in foetal life and subsequently, although

maternal androgens may well play a part. It can be shown clinically and by hormone assay that an excess of adrenal androgens is secreted after birth. Androgens produce enlargement of the clitoris or phallus, enlargement of the prostate, atrophy of the testes by inhibiting pituitary gonadotrophins, growth of facial and bodily hair and muscular development with relatively broad shoulders. Testicular pseudo-hermaphroditism, due to excessive secretion of adrenal androgens, is less definite an entity.

Main clinical types (A) **OVARIAN PSEUDO-HERMAPHRODITISM**—The female pseudo hermaphrodite possesses ovaries, but has a masculine configuration, with the external genitals simulating those of the male. The basis of the condition is difficult to explain unless it is assumed that it is comparable to the adrenal virilism of the adult, and due to hyperfunction of the adrenal cortex commencing in foetal life. Although to be within our definition such cases should show abnormalities at birth, these may not be gross until later childhood and may be further accentuated at puberty. The psychic and sexual behaviour of the pseudo hermaphrodite varies in different individuals, and is often independent of the physical or endocrine basis. Thus the hirsute, testicular pseudo-hermaphrodite may be essentially feminine in outlook and libido, and capable of functioning to complete satisfaction of herself and partner in coitus. Some are ambisexual. Apart from indisputable pseudo-hermaphrodites, it is obvious that a number of people have the physical characteristics (apart from genitals), emotional reactions and libido of the opposite sex.

(B) **TESTICULAR PSEUDO HERMAPHRODITISM**—The commonest and most easily understood type is the male in whom the formation of the external genitals is incomplete, the two scrotal folds remaining ununited (cf hare lip) and enclosing a vagina like cavity, one or more inches in depth. The penis may be incomplete, or hypospadias of varying degree may be present, or the penis may be so inadequately developed as to represent a clitoris. The patient is then brought up as a girl, until the appearance of masculine hair at puberty and the failure to menstruate lead to further investigation. The vagina is found to be false, the uterus absent and the gonads testicles. The last, being retained in the abdomen, have the characteristics of cryptorchid testicles, namely, absence or destruction of the spermatic tubules, and increase in the interstitial cells. Nevertheless, the secretion of male hormone may be deficient, and the patient be of eunuchoid type. Chapple has described the case of a young, beautiful woman, with no hirsutism, with a female figure, well-developed breasts and normal feminine libido, who in spite of a short vagina had satisfying intercourse with males. She came under observation for painful lumps in the groin, which were found to be testicles. No uterus could be detected. It is more usual, however, for the testicular pseudo-hermaphrodite to have hirsutism and other secondary male sexual characteristics. It is difficult to understand why, of two pseudo hermaphrodites with testes and female external genitals, one should have male hair and bodily form and another be a beautiful female. Obviously the genetic factors are more important than the endocrine. As regards the sexual organs other than the gonads there is considerable variation, e.g. hypospadias only, with a vagina, with a vagina and Fallopian tubes, with a vagina, uterus and tubes. The testes may be in the pelvis, the inguinal canals, the labia or in the scrotum.

Diagnosis—The recognition of pseudo hermaphroditism is not difficult, although it may not become evident to the lay person until late childhood or puberty. Urethroscopy may give evidence of value. In adrenal pseudo-hermaphroditism there is a common urogenital sinus, without a separate external urethra. In addition, if the excretion of 17-ketosteroids in the urine is appreciably raised, the adrenal origin of the condition can be strongly suspected. The elucidation of the underlying pathology may, however, be impossible unless laparotomy is undertaken. Many patients present themselves with lumps in the inguinal canal, and it is only after removal and section of these gonads that the real sex can be determined. When

pseudo-hermaphroditism is due to excess of adrenal androgens there may be attacks of adrenal insufficiency of Addisonian type, occurring either spontaneously or during the course of infections. Some, however, are more prone to attacks of hypoglycæmia. The probable explanation in both cases is that the androgen-secreting cells have displaced those which secrete the mineralocorticoids and glucocorticoids.

Prognosis.—When the disorder is due to an excess of adrenal androgens it may be modified by cortisone or bilateral adrenalectomy before puberty.

Treatment.—If help is not sought before adult life, treatment should depend upon the sexual inclinations of the patient. If these are female, the clitoris should be amputated and, if necessary, the vagina enlarged. The removal of testes may diminish the hirsutism. In the child the removal of testes would prevent hirsutism, but in view of some testicular pseudo-hermaphrodites having beautiful feminine configuration without hirsutism and the fact that the testis does secrete æstrogens, it is considered by some better to wait until puberty gives an indication of what is likely to develop. When the outlook and libido are masculine, a plastic operation can repair or create a scrotum and abolish the hypospadias.

Pseudo-hermaphroditism due to excessive secretion of adrenal androgens can be treated with cortisone or bilateral subtotal adrenalectomy. This operation should be performed before puberty, and when it proves inadequate it may still render the condition more susceptible to moderate doses of cortisone. Cortisone acts by suppressing the secretion of androgens by the adrenal. It also prevents attacks of adrenal insufficiency, although, surprisingly, these attacks are also abolished or minimised by bilateral subtotal adrenalectomy.

CUSHING'S SYNDROME

Definition.—A condition of plethoric adiposity of the face and trunk, associated with weakness, hypertension, diabetes, scanty menstruation, osteoporosis, red lineæ distensæ and a negative nitrogen balance.

Ætiology.—It is more common in females. It often begins during pregnancy but occurs also at puberty and the menopause. It may occur at any age. The symptoms are due to hypersecretion of glucocorticoids by the adrenals. Androgens are also secreted in excess in some cases.

Pathology.—There may be adrenal cortical hyperplasia, an adenoma or a carcinoma. In simple hyperfunction the size, weight and even histology of the adrenals may be normal. Nodular adrenals, due to adenomata, may be found in children. When there is a neoplasm in one adrenal the opposite gland may be atrophied, as excess of cortisone in the blood inhibits the secretion of pituitary corticotrophin. Cushing found a pituitary basophil adenoma in some patients and postulated this as the primary lesion, but the finding is by no means constant. Crooke found hyalinisation and vacuolisation of the pituitary basophil cells in all cases, but these changes are produced by an excess of cortisone in man and experimental animals and are not ætiological. However, in the case of adrenal hyperplasia, the primary stimulus is probably the pituitary and an excess of corticotrophin has been found in the plasma (Parrott). The source of corticotrophin is probably the transitional basophil cells but the eosinophils are also implicated, as in acromegaly. There are probably two varieties of corticotrophin. An ovarian tumour consisting of adrenal cortex type cells, may rarely cause Cushing's syndrome; and carcinoma of the thymus has been found. The liver is loaded with fat. The pancreatic islet cells are hypertrophic in the young.

Symptoms.—The face is rounded, plethoric and adipose. Fat is also deposited on the chest, the breasts, the buttocks and the abdomen. The distal extremities are thin, except in children, and even the thighs and upper arms may have lost fat. Thus

there is mobilisation as well as deposition of fat. Not all patients are grossly fat. The breasts may be enlarged and aerocyanosis may be a conspicuous feature. Red or purple lineæ distensæ are often present on the lower abdomen, in the groins, the lumbar regions, the axillæ and on the breasts, but they are not constant. There may be amenorrhœa or impotence and the latter may be associated with gynæcomastia and testicular atrophy. Hirsutism is found in women when there is also excessive secretion of adrenal androgens. Muscular weakness and osteoporosis are associated with excessive catabolism of protein and a negative nitrogen balance. Parathyroid function is usually normal.

The bones are rarefied and softened, so that the vertebræ are compressed, and the patient develops kyphosis and round shoulders, with a diminution in height. Lordosis helps to accentuate an adipose pendulous abdomen, and may give rise to troublesome backache; but sometimes pathological fractures of the vertebræ and ribs have escaped attention. The blood pressure is raised, and there may be a secondary ischæmic nephritis. In a few patients, fatal malignant nephrosclerosis has been recorded. Diabetes mellitus may be present in varying degrees of severity, and those patients who manifest no diabetic symptoms invariably show a delayed fall in blood sugar in the carbohydrate tolerance test. Pigmentation of the orbits and nipples may be present. Migrainous headaches are not infrequent, but changes in the optic nerves or visual fields are rare, since basophil adenomas are usually microscopic in size. The thyroid gland may be enlarged, but there is rarely evidence of hyperthyroidism.

Complications.—The patients are liable to intercurrent infections, due especially to staphylococci.

Diagnosis.—The clinical picture is not difficult to recognise. Osteoporosis can be shown radiologically and the sella turcica is rarely enlarged. Perirenal insufflation may reveal an adrenal tumour and, when the kidney is displaced, depression of the renal calyces may be demonstrated in the intravenous pyelogram. An excess of urinary 11-oxysteroids (glucocorticoids) may be shown by the Talbot copper reduction method, formaldehydogenic assays or chromatography, and methods of assay of blood corticosteroids are being evolved. 17-ketosteroid excretion in the urine is usually normal; high values suggest neoplasm. A relative polymorphonuclear leucocytosis, absence of eosinophils, a low blood potassium and alkalosis are found in some cases. The serum calcium and phosphorus are normal but the phosphatase may be raised.

Prognosis.—The condition is usually progressive, ending in death from cardiac failure or intercurrent infection.

Treatment.—An adrenal or ovarian tumour should be removed. When there is no tumour, irradiation of, or the insertion of, radon seeds into the pituitary may cause improvement or recovery. The author believes, however, that subtotal adrenalectomy is the treatment of choice. The operation can be done in one stage with two lumbar incisions. One-eighth of the adrenal gland is left behind. Cortisone, 200 mg. daily by mouth, is given the day before operation and continued for 5 days. The dose is then gradually reduced. Adrenal insufficiency is indicated by anæmia, anorexia, nausea, weakness and rapid pulse. Autogenous adrenal grafts, which have been stored at very low temperature, can be inserted in such cases, although cortisone should still be given in the acute stage. Cortisone should also be prescribed when an adrenal tumour is being removed, since the opposite adrenal may be atrophic. Cortisone has made adrenal surgery safe and is invaluable.

ADRENAL MEDULLARY TUMOURS

Three distinct types of tumour arise in the adrenal medulla; phæochromocytoma, derived from chromaffin cells, neuroblastoma, derived from embryonic sympathetic nerve cells, and ganglioneuroma, derived from adult ganglion nerve cells.

PHŒOCHROMOCYTOMA

Synonyms.—Paraganglioma; Hyperadrenalism.

Definition.—A condition in which there is excessive secretion of adrenaline and nor-adrenaline by an adrenal medullary tumour, arising from the chromaffin cells in the adrenal medulla, or occasionally from ectopic chromaffin cells in other parts of the body, e.g. para-aortic, thoracic or cervical.

Ætiology.—This is unknown. A small percentage of cases are bilateral.

Pathology.—The tumours are usually innocent, only a small percentage being malignant; but even when malignant, such tumours rarely metastasise. They are usually, but not invariably, small and the size of the tumour is no indication of its degree of functioning. The cells stain yellow with salts of chromic acid as in the case of the chromaffin cells of the normal adrenal medulla. Phæochromocytomata secrete adrenaline and nor-adrenaline in quantities greatly in excess of normal and the secretion may be continuous or paroxysmal. The proportion of adrenaline and nor-adrenaline secreted varies in different cases and cannot be predicted on clinical grounds. Their pharmacological actions are not identical, and perhaps the most important difference is that adrenaline causes acceleration and nor-adrenaline slowing of the pulse. Nor-adrenaline also differs from adrenaline in having a relatively slight glycogenolytic action. Both can be extracted from the tumours. In the clinical description, the term adrenaline will be used to include both adrenaline and nor-adrenaline, unless otherwise specified.

Symptoms.—Characteristically these are due to paroxysmal secretion of excess adrenaline which floods the blood-stream, producing a hypertensive crisis. Attacks may occur at any time with variable intervals. The systolic blood pressure may rise from 130 to 300 mm. and the change in the diastolic is usually of a smaller order. Other features are sub-sternal pain or angina, pallor, perspiration, nausea, vomiting, agonising headaches, cold clammy hands which are sometimes cyanosed, shivering, cramps of the calf muscles, mydriasis, pyrexia, anxiety and fear of death. The beat of the heart may be so forceful as to shake the chest and the bed. Tachycardia is common, but bradycardia occurs in some cases. There may be left ventricular failure with cardiac asthma. The thyroid is not uncommonly enlarged during an attack. Sweating is often a prominent and characteristic feature, although sweat glands are said to be cholinergic and not adrenergic. The fundi may show papilloedema, retinal hæmorrhages and exudates. The urine may be normal but frequently contains albumin and granular casts. Malignant nephrosclerosis has been recorded. The basal metabolic rate is increased in attacks and there is often pyrexia. Leucocytosis also occurs. The paroxysms last for 5 to 30 minutes and the patient is left in a state of exhaustion from which it may take hours, or days, to recover.

In other cases, as has been indicated above, the excessive secretion of adrenaline is constant and the condition may resemble essential hypertension or malignant progressive hypertension. Where paroxysmal attacks are added to a pre-existing chronic hypertension, the dangers of such attacks are obviously greater. Although emotion, excitement, straining at stool, exertion and other happenings may precipitate an attack, there is often no obvious initiating factor.

Diagnosis.—The condition can occur at any age and in either sex. The diagnosis can be made, with a considerable degree of certainty in the paroxysmal variety, on the basis of the clinical picture. Tomography or intravenous pyelography may provide confirmation, at the same time indicating the site of the tumour which, strangely, is much more common on the right side than on the left. Peri-renal insufflation is inadvisable because it may precipitate an attack. The same applies to attempted manipulation in the lumbar area for this express purpose, although it is rare for it

to be successful in producing an attack. During paroxysms, there is hæmoconcentration with increased hæmoglobin and hæmatocrit values and the serum potassium may be raised.

When a phæochromocytoma is present the intravenous injection of 0.025 mg. of histamine di-phosphate in 2.5 ml. of normal saline will cause an enormous rise of blood pressure, sometimes amounting to a hypertensive crisis, which is one reason for avoiding the test unless the diagnosis on clinical grounds is improbable. Its mechanism of action is unknown. A simple and safe test, evaluated by Pickering and colleagues, is the measure of heat elimination from the hand by the change of temperature of water in a calorimeter in which the hand is immersed. Because of vasoconstriction the calories produced, under comparable standard conditions, are approximately only one-third of the normal. Another type of test depends on the use of adrenergic blocking substances like piperoxane and dibenamine, which have a greater affinity for the adreoline receptor end organ than has adrenaline. Thus they both produce a fall of blood pressure, in the presence of a phæochromocytoma, in contrast to the mild increase in blood pressure which occurs when hypertension is not due to adrenaline. Both are injected intravenously and are preferably added to a slow intravenous saline infusion. Piperoxane is injected in doses of 0.25 mg. per kg. body weight over a period of 2 minutes. It may also be given in 2 ml. of normal saline injected slowly and the maximum dose should not exceed 20 mg. The injection may have to be stopped because of headache, nausea or sub-sternal pain. Dibenamine hydrochloride is given in doses of 7 mg. per kg. of body weight dissolved in 300 ml. of a 5 per cent. solution of glucose in normal saline over a period of 1 hour. The fall of blood pressure lasts for 24 hours and this makes it suitable also for therapeutic control. This also applies to phentolamine (Regitin), given in doses of 0.08 mg. per kg. body weight during 1 to 2 minutes. It produces a rapid fall of blood pressure which lasts a few hours. These various adrenergic substances have clinical formulae very closely related. Another test, which has been developed by Peart and colleagues, based on the work of Euler and Goldenburg, is the measurement of adrenaline-like pressor substances in the urine. After hydrolysis with hydrochloric acid, so that only the free amines are estimated, these are selectively adsorbed on alumina. They are assayed biologically, using the blood-pressure response of the anaesthetised rat and measuring the response against known solutions of adrenaline and nor-adrenaline. The fact that dihydro-ergotamine reverses the action of adrenaline but not that of nor-adrenaline permits a measurement also of the relative quantities of each. This ratio varies considerably in different cases. As an indication of the value of this test the quantity of pressor amines, found in the presence of a phæochromocytoma, may be 10 to 40 times that in control cases or in the same case after operation. It is much more reliable than the adrenergic blocking test which may give unreliable results in some cases for no apparent reason.

Treatment.—The tumour should be removed. During its manipulation there may be a rapid and dangerous rise of blood pressure which can be controlled by piperoxane, the effect of which lasts some 15 minutes. After removal of the tumour there is a dangerous drop in blood pressure and this is controlled by nor-adrenaline in strength of 10 to 20 mg. per litre of normal saline, the rate being adjusted according to the blood pressure. Atropine should not be used before operation, as it appears to interfere with the response to nor-adrenaline. In some patients the ultimate blood pressure after operation does not fall to normal and in others it may continue to rise. If assays of urinary adrenaline become normal, any residual hypertension can be attributed to irreversible changes in the peripheral vascular system. Even so, the general symptoms and the fundi always show improvement. If, however, adrenaline is still present in high concentration in the urine, a tumour on the opposite side should be suspected.

PHŒOCHROMOCYTOMA

Synonyms—Paraganglioma, Hyperadrenalism

Definition.—A condition in which there is excessive secretion of adrenaline and nor-adrenaline by an adrenal medullary tumour, arising from the chromaffin cells in the adrenal medulla, or occasionally from ectopic chromaffin cells in other parts of the body, e.g. para aortic, thoracic or cervical

Ætiology—This is unknown. A small percentage of cases are bilateral

Pathology—The tumours are usually innocent, only a small percentage being malignant, but even when malignant, such tumours rarely metastasise. They are usually, but not invariably, small and the size of the tumour is no indication of its degree of functioning. The cells stain yellow with salts of chromic acid as is the case of the chromaffin cells of the normal adrenal medulla. Phæochromocytomata secrete adrenaline and nor-adrenaline in quantities greatly in excess of normal and the secretion may be continuous or paroxysmal. The proportion of adrenaline and nor-adrenaline secreted varies in different cases and cannot be predicted on clinical grounds. Their pharmacological actions are not identical, and perhaps the most important difference is that adrenaline causes acceleration and nor-adrenaline slowing of the pulse. Nor-adrenaline also differs from adrenaline in having a relatively slight glycogenolytic action. Both can be extracted from the tumours. In the clinical description, the term adrenaline will be used to include both adrenaline and nor-adrenaline, unless otherwise specified.

Symptoms—Characteristically these are due to paroxysmal secretion of excess adrenaline which floods the blood stream, producing a hypertensive crisis. Attacks may occur at any time with variable intervals. The systolic blood pressure may rise from 130 to 300 mm and the change in the diastolic is usually of a smaller order. Other features are sub sternal pain or angina, pallor, perspiration, nausea, vomiting, agonising headaches, cold clammy hands which are sometimes cyanosed, shivering, cramps of the calf muscles, mydriasis, pyrexia, anxiety and fear of death. The beat of the heart may be so forceful as to shake the chest and the bed. Tachycardia is common, but bradycardia occurs in some cases. There may be left ventricular failure with cardiac asthma. The thyroid is not uncommonly enlarged during an attack. Sweating is often a prominent and characteristic feature, although sweat glands are said to be cholinergic and not adrenergic. The fundi may show papilloedema, retinal hæmorrhages and exudates. The urine may be normal but frequently contains albumin and granular casts. Malignant nephrosclerosis has been recorded. The basal metabolic rate is increased in attacks and there is often pyrexia. Leucocytosis also occurs. The paroxysms last for 5 to 30 minutes and the patient is left in a state of exhaustion from which it may take hours, or days, to recover.

In other cases as has been indicated above, the excessive secretion of adrenaline is constant and the condition may resemble essential hypertension or malignant progressive hypertension. Where paroxysmal attacks are added to a pre-existing chronic hypertension the dangers of such attacks are obviously greater. Although emotion, excitement, straining at stool, exertion and other happenings may precipitate an attack there is often no obvious initiating factor.

Diagnosis—The condition can occur at any age and in either sex. The diagnosis can be made with a considerable degree of certainty in the paroxysmal variety, on the basis of the clinical picture. Even so the general symptoms and the fundi always show improvement. If however, adrenaline is still present in high concentration in the urine, a tumour on the opposite side should be suspected.

sexual characteristics are well developed or when nocturnal erections and ejaculations are experienced. Impotency associated with diabetes mellitus is believed to be due to local neuro-vascular pathological changes rather than to deficiency of any androgenic hormone. The commonest cause of impotence is psychological and wherever there is no obvious organic defect, psychological impotence should be strongly suspected. It is a form of sexual neurosis and is usually only part of a general neurosis or anxiety state. Temporary lack of libido and impotence are by no means uncommon and respond to lessening of the strain and effort of daily life, where such is possible, and to reassurance and encouragement. More severe forms of psychological impotence are often refractory to any form of psychotherapy. Testosterone, or methyl testosterone, will produce an almost immediate response in cases of impotence due to deficient secretion of testosterone, but will be ineffective in cases of psychological impotence. This can be used as a therapeutic test in doubtful cases.

Sterility in the male can be due to azoospermia or oligospermia. Biopsy of the testes will show destruction or disorganisation of the seminiferous tubules but the interstitial cells are intact and functioning well. The commonest cause is mumps but any infection may be responsible. The seminiferous tubules are much more sensitive to toxins than are the interstitial cells. Apart from a drastic decrease in the number of sperm cells, the deficiency or absence of motility and a high percentage of abnormal shapes are evidence of probable infertility. By the nature of the pathological lesion, hormone therapy is unlikely to be effective in male sterility. It is prudent never to declare a patient completely sterile but to use the term "relative infertility".

CLIMACTERIC

Synonym—Menopause

Definition—The climacteric, or "change of life", occurs in women about the age of 45 to 50, and its manifestations are due to the cessation of ovarian function and associated changes in the pituitary and adrenal glands. Menopause refers more precisely to the cessation of menstruation. It is one feature of the climacteric.

Ætiology—The primary disorder appears to be cessation of ovarian activity, the ovaries ceasing to respond to gonadotrophic stimuli. There is a secondary hyperactivity of the anterior pituitary gland and of the adrenal cortex. The pituitary secretes an excess of follicle-stimulating hormone, but apparently ceases to secrete luteinising hormone. The ovaries become atrophic and fibrosed.

Symptoms—A great deal depends on the endocrine constitution of the individual. Some women experience almost no symptoms or signs. Others may suffer severe disturbance. Vasomotor instability is manifested by hot flushes over the face and neck, alternating with cold sweats. There is an increase in fat and weight sometimes very considerable. Hair may grow or increase on the lips and chin, a manifestation of increased activity of the adrenal cortex. Anxiety, nervousness, irritability, emotional tremors and palpitations, may change personality and behaviour pattern. Hypertension may develop at this time, and may disappear spontaneously after months or years, or may be permanent. Pruritus is often troublesome. Many diseases, such as exophthalmic goitre, diabetes mellitus, rheumatoid arthritis and migraine, may have their onset at this time of life although not necessarily caused directly by the endocrine changes occurring at the climacteric.

The climacteric changes and symptoms often go on for a period of several years and may even recur after an interval of several years' freedom from disturbance. That they are not entirely brought about by cessation of ovarian activity is indicated by the effects of bilateral ovariectomy in younger women, e.g., 30. The operation may or may not be followed by climacteric symptoms, but in any case at the age of 45 to 50, although menstruation ceased 15 years previously, climacteric symptoms may make their appearance.

Prognosis.—Vasomotor, neurotic and hypertensive symptoms tend to disappear spontaneously after some months or years, but adiposity and hirsutism may remain.
